Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www3.interscience.wiley.com/aboutus/journal_ordering_and_payment.html#Tax. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/journal-info.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit www.interscience.wiley.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (Americas); +44 (0) 1865 778315 (Europe, Middle East, and Africa); or +65 6511 8000 (Asia Pacific). Subscription in 2010 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from csjournals@wiley.com. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. This journal is available online at Wiley InterScience. Visit www3.interscience.wiley.com to search the articles and register for table of contents e-mail alerts.

Access to this journal is available free online within institutions in the developing world through the HINARI initiative with the WHO. For information, visit www.healthinternetwork.org

Journal Customer Services: For ordering information, claims and any enquiry concerning your journal subscription, please go to interscience.wiley.com/support or contact your nearest office:

In This Issue

Effects of Disaster and Victimization

In a study of more than 2,000 American children ages 2–17, **Becker-Blease, Turner, and Finkelhor** (p. 1040) looked at the effects of victimization (human-caused harm such as maltreatment, abuse and neglect, and assault) and disaster (one-time or ongoing events such as hurricanes and earthquakes that produce stress). Almost 14% of the children had experienced lifetime exposure to disaster, whereas more than 4% had been involved in a disaster in the past year. Children who were exposed to victimization only or to both disaster and victimization had higher levels of anxiety, depression, and aggression than those who were not exposed. By providing the first prevalence and incidence estimate of disasters in a nationally representative sample of U.S. children, the study helps us understand the interactions among various kinds of stressful events.

Researchers who work in areas where people have been harmed by disasters often focus solely on the impact of direct exposure to the disaster. **Fernando, Miller, and Berger** (p. 1192), in their study of tsunami survivors in Sri Lanka, argue that it is important to consider the role of daily stressors as well. Looking at more than 400 Sri Lankan youths ages 11–20, they find that while war and disaster had a direct effect on youths' psychological health, daily stressors—including poverty, family violence, and lack of safe housing—represented major sources of ongoing stress. By making sure not to miss the importance of ongoing stressors in youths' daily lives, the study highlights the need for holistic policies and programs that focus on reducing these current stressors.

Millions of children are affected by man-made disasters such as having their homes destroyed or losing a parent, but most research focuses on survival and physical well-being, overlooking the social and emotional impacts. In a longitudinal study, **Kithakye, Morris, Terranova, and Myers** (p. 1114) looked at these factors among more than eighty 3- to 7-year-old children who experienced political conflict in Kenya; data were collected before and after the conflict. As expected, children with worse conflict experiences were more likely to have more social and emotional difficulties, specifically more aggressive behavior and less positive, prosocial behavior. Children who were able to adapt their emotional responses and control their emotions were better able to cope with the conflict. The findings have implications for those working to help child victims of conflict.

Experiences From 9/11

Chemtob et al. (p. 1129) took a longitudinal look at preschoolers exposed to the September 11 attacks in New York City. Were children ages 5 or younger whose mothers suffered from posttraumatic stress disorder (PTSD) and depression as a result of the terrorist attacks more likely to have behavior problems than children of moms with neither PTSD nor depression, or with only depression? In their 21-month study of more than 100 moms and their youngsters who were directly exposed to the attacks, Chemtob et al. find that moms who had PTSD and were depressed (compared to those who were only depressed or had neither disorder) were much less likely to be able to help their children regulate their emotions and behavior. As a result, the children were more likely to have problems such as aggression, anxiety, depression, and difficulty sleeping. In suggesting that very young children are highly sensitive to their parents, the findings point to the value of identifying at-risk youngsters through their mothers' experiences.

Did exposure to the 9/11 attacks among adolescents and moms living in New York City result in lasting mental health problems such as posttraumatic stress syndrome (PTSD) and depression? Did it affect social attitudes a year after the attacks? **Gershoff, Aber, Ware, and Kotler** (p. 1142) studied more than four hundred 12- to 20-year-olds and their moms. They were surprised to find that a year after 9/11, exposure to the terrorist attacks did not have a significant effect on the youths' and their mothers' mental health. However, there were elevated levels of problematic mental health symptoms among the mother–child pairs, suggesting that something other than the trauma of 9/11—perhaps everyday stress and trauma—is involved. The

study also finds that exposure to 9/11 appears to have prompted families to have more discussions about serious social and political issues, including mistrust and prejudice toward immigrants.

Child Exposure to Wars and Disasters

Children are the most vulnerable group for harmful long-term psychological consequences of violence and destruction. In Sri Lanka, residents living in the northeast have been affected by a civil war as well as the 2005 tsunami. **Catani et al.** (p. 1176) sought to determine what happens to children when various risk factors pile up. In their study, children in the resource-poor country were affected by both armed conflict and a natural disaster, and many also coped with domestic violence. The epidemiological study, of almost 1,400 Tamil children ages 9–15, used data from four cross-sectional studies. Findings: All of the adverse experiences contributed significantly to children's difficulties adapting. Particularly stressful were very severe exposure to trauma and loss of family support through violence or death. The findings have implications for efforts to protect traumatized children in developing countries.

Traumatic events that occur during wars and disasters create widespread mental health problems for young people and their families that often outstrip available mental health resources. Currently, clinicians cannot predict which youths will recover on their own and which will require intervention in order to recover. **Layne et al.** (p. 1053) studied 880 secondary-school students (ages 13–19) in Bosnia 5 years after the end of the Bosnian civil war, measuring the types of war trauma to which the students had been exposed. Then they identified the types of exposure that were most likely to lead to mental distress. By developing a way to identify which high-risk youths and their families are most likely to need mental health services, the study provides tools for clinicians involved in helping war-exposed youths.

Child Soldiers

Despite international bans, more than 250,000 children are exploited as soldiers worldwide, almost half of them in Africa. In a study of former Ugandan child soldiers, **Klasen et al.** (p. 1096) looked at 330 children ages 11–17. Most were exposed to shooting and beaten by armed forces, half had killed, and a quarter had been raped. A third suffered from PTSD, more than a third were depressed, and more than half had behavioral and emotional problems. Despite their exposure to severe trauma, however, a third of the former child soldiers exhibited posttraumatic resilience as indicated by the absence of clinically significant mental health problems. Why? Once they returned from war, these children had less exposure to violence in their homes and communities, fewer feelings of survivor guilt, less motivation to seek revenge, better socioeconomic situations, and more perceived spiritual support, according to the study. The findings have implications for developing policies and programs for the two thirds of child soldiers who continued to be exposed to violence once they returned home and suffered from significant mental health problems.

In separate research, the first longitudinal study of psychosocial adjustment in former child soldiers involved in Sierra Leone's bloody civil war, **Betancourt et al.** (p. 1077) looked at more than 150 children ages 10 and 18, mostly male, over 2 years. They find that children who injured or killed others in war were more hostile than children who had not done so and that those who survived rape were more anxious and hostile, suggesting that these categories of war trauma are highly toxic to children's psychosocial adjustment. They also find that children who were abducted at a young age were more depressed than those taken later. Children living in communities in which they felt accepted were less depressed and more confident, and children who stayed in school had better attitudes and behaviors. For the children in at least 86 countries who have been abducted and forcefully conscripted into armed forces, this study has implications for long-term treatment.

Earthquake After-Effects

In 1999, two major earthquakes shook provinces in Turkey. To explore the long-term effects of the disasters, 2 years after the natural disaster, **Celebi Oncu and Wise** (p. 1161) studied more than fifty 7-year-old children who had been affected by the earthquakes; the children were asked to complete stories that involved stressful situations. A control group of 50 children who did not experience the earthquakes also completed stories. Children who had been through the earthquakes provided more negative story endings than their peers, especially when they felt they could not change the course of events, suggesting that the effects of trauma are long-lasting.

In the Aftermath of Katrina

Hurricane Katrina struck the Gulf Coast in August 2005, affecting countless children and families. Recovery from the storm was slow, and many children experienced ongoing stressors that resulted in a range of trauma responses. Three studies in this issue address Katrina survivors.

In a longitudinal study of recovery patterns of children affected by Katrina, **Kronenberg et al.** (p. 1241) find that most of the almost 400 elementary- and high-school-aged children they surveyed did not display long-term psychological problems. For most, trauma symptoms such as feeling depressed, sad, nervous, as well as having trouble concentrating and sleeping, declined over time. Moreover, children and adolescents showed enormous strengths, largely, the study finds, because of supportive relationships and rebuilt schools. But this work in progress finds that more than a quarter of the children continued to have significant trauma symptoms of posttraumatic stress and depression 3 years later. Children who reported these symptoms were more likely to be younger and female, have seen a mental health professional, and have reported family or school problems. Continued study of these children will provide further insights into resiliency.

Kilmer and Gil-Rivas (p. 1211) explored what qualities of children and their relationships with their primary caregivers relate to posttraumatic growth—the positive changes that occur as a result of struggles with trauma. In their longitudinal study, they interviewed more than fifty 7- to 10-year-olds affected by Hurricane Katrina, asking about children's views of themselves, how their thoughts influenced their reactions to the trauma, and the role of their caregivers after the hurricane. Findings: Certain types of thoughts and feelings can lead to posttraumatic growth; in particular, both negative, recurrent, distressing thoughts and constructive, repetitive thinking play a role, suggesting that discomfort combined with reflective processes can lead to positive change. Furthermore, while neither caregivers' warmth nor their distress affected growth, caregivers' coping advice encouraging children to look for the positive did. The study sheds light on our understanding of posttraumatic growth in children and can help those working with youth after trauma.

Vigil, Geary, Granger, and Flinn (p. 1228) studied the effects of Katrina from the standpoint of gender. Experiencing distress is a normal part of life, yet males and females have been found to show different patterns of stress reactions in laboratory studies. In their study of more than 60 teens displaced by Hurricane Katrina and living in a government relocation camp, the researchers measured psychological functioning (such as depression and aggression) and two hormone markers of stress regulation (salivary cortisol and α-amylase), then compared these with more than 50 adolescents who were demographically similar but lived in a different part of the United States that was not affected by Katrina. Vigil et al. find that male and female teens who experienced the hurricane showed distinct patterns of behavioral stress as well as gender differences in how they regulated physiological stress. Specifically, compared to the children who were not exposed to Katrina, girls were more depressed and boys exhibited lower levels of aggression and higher levels of confidence. In suggesting that males and females developed specialized systems for processing and responding to stress, the study adds to our understanding of stress regulation following trauma.

Disaster and Disabilities

Disasters affect nearly 70 million children worldwide each year; about a 10th of those children have disabilities, and more acquire disabilities as a result of disaster. In a review of research on how individuals with disabilities cope with disaster and how children are affected by disaster, **Peek and Stough** (p. 1260) find the following: Children with disabilities are more likely to be poor and live in low-quality housing, boosting their exposure to hazards. When disaster strikes, children with disabilities may have a more difficult time taking action, escaping from, or withstanding the force of the event. Even when evacuation occurs successfully, children with disabilities and their families may be less likely to leave the threatened area. Children with disabilities also encounter barriers during emergency response and recovery phases. And they face special challenges postdisaster when separated from their parents, teachers, or other support professionals. This commentary can help inform disaster-preparedness and response efforts for children with disabilities and their caregivers.

Best Practices

How should children be cared for and protected in humanitarian crisis situations? **Ager, Stark, Akesson, and Boothby** (p. 1271) asked 30 specialists from leading organizations responsible for the care and protection of children in humanitarian crises worldwide to identify best practices to inform and improve future programs for children. Consensus was reached on 55 statements, including the need to coordinate among agencies, involve the community in promoting child well-being and development, and be culturally sensitive to different views of childhood in different countries. Responses suggested that two ideas from child development research—resilience and social ecology—have most influenced current views of best practices, but the researchers suggest that findings from developmental science needed to be more clearly communicated to practitioners and policy makers so they can be used in programming.

Linguistics and Labeling

At 14 months, children accept minimal pairs (words that differ by a single phoneme, like *daw* and *taw*) as labels for the same object. By 20 months, they are less likely to make this mistake due to their experience with phonemes in different word forms. **Thiessen and Yee** (p. 1287) sought to determine how widely 15-month-olds generalize knowledge from previous experience. They find that the effect of training is limited, at least initially, to contexts that are very similar to the initial experience. This suggests that children's early word-form representations are at least partially context specific.

Eyes, Ears, Nose, and Mouth

Decoding facial emotions is critical to allowing us to evaluate others' states of mind and intentions. **Vlamings, Jonkman, and Kemner** (p. 1304) studied 70 Dutch 3- to 8-year-olds to investigate the role played by different brain systems in the perception of faces and facial expressions. Children showed enhanced early visual brain responses to fearful faces compared to neutral faces, as do adults. But for the children, the brain's responses to expression appeared to be driven by a different visual pathway than that used by adults. While adults typically process faces using a visual pathway that relies on coarse information such as shading, distance between eyes, and hairlines (low spatial frequency cues), the children appeared to be using a system that relies on finer details and features (high spatial frequency cues). The finding that children process faces using different pathways than adults has implications for various theories regarding the nature of face processing across development, and may be relevant for our understanding of developmental disorders such as autism.

Family Functioning

Guided by family systems theory, **Sturge-Apple, Davies, and Cummings** (p. 1320) took a longitudinal look at how family relationship patterns affect children's adaptation to school. They studied more than 225 mostly European American families with 6-year-old children over a 3-year period to first identify three types of families—cohesive, disengaged, and enmeshed. Then they determined how these types of families affected children's adjustment to school. Children in disengaged families had the most difficulty adjusting to school, with higher levels of aggression and delinquent behavior in the classroom, and they continued to have these problems over the 3 years of the study. Children in both disengaged and enmeshed families had higher levels of depression and anxiety, and more difficulty emotionally adjusting to school over the course of the study. The research identifies new ways to analyze how families function and offers insights into young children's adjustment to school.

Disasters and Their Impact on Child Development: Introduction to the Special Section

Ann S. Masten
University of Minnesota, Twin Cities

Joy D. Osofsky
Louisiana State University Health Sciences Center, New Orleans

Disasters touch the lives of millions of children every year in many forms. These include natural disasters such as earthquakes, hurricanes, tornadoes, fires, or floods; human-made disasters of armed conflict, genocide, industrial accidents, or terrorism; and disease outbreaks. Interest in the impact of disasters on children among scientists dates back decades to the beginnings of research into risk and resilience in development (Garmezy, 1985; Garmezy & Rutter, 1983). For many years, only a small number of scattered studies of disasters were published on young people, often in the wake of a major catastrophe, such as the Buffalo Creek disaster (Erikson, 1978; Green et al., 1991; Newman, 1976), World War II and the Holocaust (Freud & Burlingham, 1943; Moscovitz, 1985), or a major fire (McFarlane, 1987). In the beginning of the 21st century, with the rise in international terrorism, concerns about flu pandemic, an alarming sequence of natural and human-designed disasters around the world, and globalization of media coverage, there is increasing attention to the consequences of disaster for children and youth (La Greca, Silverman, Vernberg, & Roberts, 2002; Masten & Obradović, 2008; Osofsky, Osofsky, & Harris, 2007; Sagi-Schwarz, Seginer, & Abdeen, 2008). Research into disasters has accelerated despite inherent difficulties in conducting research in the context of catastrophic events. Given the importance of understanding how different types of disasters may impact development for children and families, it was timely to devote a special section of this journal to the impact of disasters on child development.

The goal of the special section on disasters and child development was to provide an opportunity for researchers around the world to examine how disasters of nature and human design might affect children of different ages, experiences, cultures, and contexts, as well as how exposure to a disaster may alter developmental processes or developmental trajectories. Potential contributors were invited to submit a letter of intent by January 15, 2008, and 67 letters for different possible contributions were received. We invited 39 potential contributors to submit full manuscripts for review by May 1, 2008. The 15 articles comprising this special section represent 22% of the submitted letters of intent and 45% of the manuscripts that were submitted for review.

The process of review was complicated by the diversity of the submissions in terms of disaster types and contexts, ages of disaster victims, nationality of authors, disciplinary approach, methods, and focus of the articles (e.g., empirical, conceptual, review, commentary). As editors for this special section, we strove to capture a broad representation of contemporary international scholarship from among the submissions that would reflect the diversity in the field. We were well aware of the challenges of conducting research in the context of disaster (discussed further below) and the constraints posed by ethical and practical dilemmas. In some cases, a study represents rare data obtained by methods that may not meet typical standards of scientific rigor because of the study context (e.g., naturalistic studies in the field or remote locations after a disaster). In all cases, we based the editorial decisions on our judgment of the potential value and unique contribution of the article in the context of current knowledge.

Correspondence concerning this article should be addressed to Ann S. Masten, University of Minnesota, 51 East River Road, Minneapolis, MN, 55455, or Joy D. Osofsky, Louisiana State University Health Sciences Center, 1542 Tulane Avenue, New Orleans, LA 70112. Electronic mail may be sent to amasten@umn.edu or josofs@lsuhsc.edu.

The articles in the special section collectively provide a picture of the state of the research into disaster and development in children and adolescents. The diversity of the articles is striking, spanning a broad array of disaster situations, including war and child soldiers, political conflict and terrorism, hurricanes and tsunami, as well as earthquakes and floods. Specific disasters occurring in nine different countries are represented. The articles include many age groups from early childhood through adolescence. Longitudinal studies continue to be rare in this domain of science as are studies that address developmental processes. Most of the articles focus on a behavioral level of function and analysis, although several articles address other levels of analysis, including biological function, relationships, and the recovery context.

In the following sections, we highlight key issues and findings arising from the special section. In the conclusion, we comment on the implications of the special section for future developmental research and applications for improving disaster response and preparedness for the well-being of young people.

Challenges of Research Into Disasters and Child Development

Research in the context of disaster is not for the faint of heart. It is extraordinarily challenging from ethical, conceptual, methodological, and practical perspectives. It can be stressful and sometimes dangerous for the investigators as well as the participants. Special ethical issues must be considered when research is conducted among groups of traumatized survivors. The authors of these articles can be commended for their courage and persistence in the face of such obstacles, as well as their sensitivity and success in executing their work.

Disasters, by their nature, pose great challenges to researchers. They often occur with little advance warning and devastation on a scale that generates many issues for research, ranging from the ethical to the pragmatic. In the immediate aftermath of a catastrophe, survival and basic needs take precedence over research and significant issues arise about the competence of recently traumatized individuals to provide informed consent to research. In addition, research conducted in sites of mass destruction with traumatized people can be both dangerous and traumatizing to those carrying out research. There can be many other kind of dangers, known and unknown, related to ongoing violence or aftershocks, exposure to contagious diseases, lack of supplies, electricity, housing, and many of the modern tools researchers often take for granted, such as offices, computers, mobile telephones, and refrigeration. Migration, chaos, and instability may follow disaster, creating enormous difficulties in tracking individuals for longitudinal studies and often resulting in substantial missing data. These issues, as well as ongoing difficulties in obtaining funding after the immediate impact of the disaster and for follow-up, may contribute to the paucity of longitudinal studies in this area.

Ideally, disaster research would include predisaster assessments, but this standard poses an enormous challenge given the unpredictability of most disasters. In a small number of studies in the literature, investigators have been able to capitalize on research already underway prior to a disaster. In the special section, a study of Kenyan children in a preschool serving 100 children was begun 4 months prior to the eruption of political violence (Kithakye, Morris, Terranova, & Myers, 2010). Follow-up data were obtained 3 months after the onset of violence for 84 of the 92 participants of the preschool study. However, in most cases, the articles of the special section focus on data collected postdisaster, as is typical in most of the extant literature.

Additional design issues confront investigators. Representative samples are difficult to access following disasters and most of the studies focus on samples of convenience or subpopulations. As indicated earlier, samples also may change over time related to instability in the disaster-affected region, leading to missing data. Epidemiological data are rare in this field, for understandable reasons. Therefore, the data provided by Becker-Blease, Turner, and Finkelhor (this issue) offer much-needed information on the prevalence and incidence of disasters in a nationally representative sample of younger children and adolescents for the United States. Data were drawn from the Developmental Victimization Survey conducted in the winter of 2002–2003 to assess the prevalence of various traumatic experiences among American children ages 2–17. About 14% of the young people had experienced some disaster event in their lifetime and around 4% in the past year. Within and across each age group studied (children ages 2–9 by parent report and youth ages 10–17 by self-report), age was associated with higher disaster exposure.

Another challenge is posed by the reality that disasters often unfold in contexts and cultures where research has not been common. One of the most important issues for developmental science in general is the fact that a disproportionate amount of research has been concentrated in more economically advanced societies and contexts convenient to scientists, such as cities and towns, particularly those near academic centers. As a result, investigators trying to study disasters and child development often are faced with challenging issues of measurement and the lack of a database on normative development in many cultures and regions of the world. Additionally, participants in developing countries may not be able to read or have no written language. There may be no relevant instruments in the language or culture of the exposed population, along with a shortage of interpreters, and limited or nonexistent validity data on the value of the tools. This situation also may be confounded by cultural differences in knowledge or support for research as well as differences in the understanding of fundamental concepts of psychological well-being and health. Cultural differences can pose other barriers of access, relevance, and understanding.

These challenges of disaster research have shaped the nature of international research on child development and disasters, and their influence is evident in the special section. It is all too easy to critique the design and methods of disaster research or to underestimate what has been achieved in an investigation if one ignores the reality of these challenges. The special section represents diverse approaches to this array of challenges, with some remarkable examples of success under extraordinarily difficult research conditions. Some investigators worked with local nongovernmental organizations (NGOs) to facilitate data collection. For example, Catani et al. (this issue) partnered with German and Sri-Lankan organizations to train 1,000 teachers in Sri Lanka before they conducted a series of epidemiological surveys of Tamil children before and after the tsunami of December 2004. Also in Sri Lanka, Fernando, Miller, and Berger (this issue) enlisted an NGO partner for their study of disaster-survivors of the tsunami and political violence. Betancourt et al. (this issue) partnered with the International Rescue Committee (IRC) to conduct their ground-breaking longitudinal study of child soldiers of Sierra Leone. This partnership made the study possible; however, the death of the IRC country director midstudy and suspension of their program also brought data collection to a halt before it was completed. In the United States, Vigil, Geary, Granger, and Flinn (this issue) conducted a study of adolescents dislocated by Hurricane Katrina beginning 3 weeks after a government trailer camp opened near Baton Rouge and 2 months after the hurricane. Their study included sampling of saliva from adolescents living in this trailer-park community, as well as a comparison group, providing a rare study of disaster in youth that included biological as well as behavioral levels of assessment. In New Orleans after Katrina, the Osofsky team was able to begin research immediately after school reopened in St. Bernard parish, just 2½ months post-hurricane, because the investigators were local and returned to the disaster area immediately to work on recovery (Kronenberg et al., this issue; Osofsky et al., 2007).

Many of the investigators had to create or translate measures that would be appropriate to the language, culture, and disaster context, relying on bootstrapping methods to demonstrate psychometric reliability or validity. A number of the investigators describe the challenges of translating and back-translating measures, while striving for cultural equivalence, or adapting measures for new contexts (e.g., Betancourt et al., this issue; Catani et al., this issue; Fernando et al., this issue; Kithakye, Morris, Terranova, & Myers, this issue; Klasen et al., this issue; Layne et al., this issue). Betancourt et al. describe the strategies used to create their measures through multiple stages of local consultation, youth focus groups, translation back and forth, and psychometric analyses. Fernando et al. conducted several "comprehensibility checks" with students in pilot schools to refine the survey instruments for their study. Layne et al. enlisted the aid of doctoral students in psychology at the University of Sarajevo to help them review their measures for cultural relevance and language accuracy for their study of Bosnian adolescents who experienced war and political violence following the collapse of the former Yugoslavia.

Most of the studies are cross-sectional rather than longitudinal, with notable exceptions (Betancourt et al., this issue; Kilmer & Gil-Rivas, this issue; Kithakye et al., this issue; Kronenberg et al., this issue). The study by Betancourt et al. represents one of the first longitudinal studies of child soldiers ever reported in the literature. The first prospective longitudinal data on a cohort of male and female child soldiers, this study constitutes a major contribution to a limited literature. Two studies of recovery and resilience among children who experienced Hurricane Katrina by Kronenberg et al. and by Kilmer and Gil-Rivas both include longitudinal data.

The challenges posed for research during the crisis phase of disaster or ongoing conflicts highlight the significance of diverse approaches to important questions for policy, humanitarian assistance, disaster planning, and intervention. These questions include the following: What is the range of human response and how does this vary by development and situation? What can and should be done to help? What works best for whom in which context? What can be harmful? One approach to the conundrum of executing meaningful research under emergency conditions to address such questions is to draw on the expertise of people with extensive field experiences. Ager, Stark, Akesson, and Boothby (this issue) have drawn on the expertise of leaders in humanitarian agencies with extensive disaster and crisis experience to generate data for a "Delphi" consensus analysis on the best practices for care and protection of young people in such crisis situations. Their strategy is more structured and systematic but similar to the convening of consensus panels to identify best practices for diagnosis or intervention (see Hobfoll et al., 2007, for results of a consensus panel on mass trauma intervention). Ager et al. note the congruence of the consensus findings on best practices with the developmental literature on ecosystems of development and resilience.

Highlights of Findings in the Special Section

The conceptual frameworks for the articles in the special section draw heavily on developmental systems theory and many of them focus on concepts of cumulative risk and resilience (Masten & Obradović, 2008). Response to disaster is often linked to the severity of exposure, described as a "dose–response gradient," to previous experiences of trauma or to the conditions of the recovery environment. Congruent with the general risk literature, symptoms or problems often are related to greater cumulative exposure, defined in terms of severity (intensity) or a piling up in time of multiple traumatic experiences. At the same time, striking variability may be observed in the range of behaviors observed in individuals following similar levels of trauma exposure, suggesting that other influences play a role in adaptation to disaster. These include individual differences, as well as differences in the supports or recovery context. Promotive or protective influences that foster resilience hold particular significance for efforts to prepare for disaster and recovery more effectively (Layne et al., 2009; Masten & Obradović, 2008).

Results converge on several important themes for understanding the effects of disaster on development. These include the significance of exposure in terms of nature and dose, the importance of pre- and postdisaster context for understanding disaster response and recovery, protective effects associated with better recovery, and the possible role of age and gender differences both for exposure and response patterns.

Dose Effects, Threshold Effects, and Unpacking Trauma

One of the widely supported findings in the literature on trauma and its consequences is the dose–response effect: As the level of extreme adversity exposure rises or accumulates, there is an increase in symptoms of trauma, behavior problems, mental anguish, and many other kinds of problems observed in children as well as in adults (Norris et al., 2002; Pine, Costello, & Masten, 2005). Similar risk gradients have been observed in diverse studies of cumulative risk and adversity in the developmental literature (Obradović, Shaffer, & Masten, in press; Shonkoff, Boyce, & McEwen, 2009).

Dose–response effects were observed in various forms in the studies of the special issue. Catani et al. (this issue) found that children in Sri Lanka exposed to the 2004 tsunami showed worse adaptation after the disaster in relation not only to more severe exposure but also as a function of higher exposure to other adversities, including the ongoing war, family violence, and other psychosocial risks. Similar findings are reported by Fernando et al. (this issue) in their study of tsunami survivors. Celebi Oncu and Wise (this issue) found differences in stories by children who were directly exposed to the 1999 Kocaeli earthquake 2 years after the disaster compared with children from a distant town in Turkey. Kronenberg et al. (this issue) found that youth with better patterns of mental health 2 and 3 years following Katrina had lower initial trauma exposure and also less recovery adversity. Additionally, the study of political conflict in Kenya, by Kithakye et al. (this issue), indicated that the severity of the disaster experience was associated with more negative and fewer prosocial behaviors.

Dose–response effects were also observed in relation to parent function by Chemtob et al. (this issue) in their study of children following 9/11 in New York City. Preschool children of parents with more symptoms of mental health problems had more problems. These results are consistent with developmental theory suggesting that children who are not protected at the time of disaster by effective caregivers may be particularly vulnerable to disaster effects. One of the mediating pathways by which disasters can harm children is via their effects on parents and parenting quality, particularly among very young children (Masten & Obradović, 2008;

Osofsky, 2004; Osofsky et al., 2007; Pine et al., 2005). Parents have a key role in the protection of children in life-threatening circumstances through actions they take related to preparedness and safeguarding their children, their communications about safety or danger, their instructions or training of children about what to do, and other means, such as their role modeling of adaptive behavior. As a consequence, an important part of disaster preparedness for children involves preparing parents to carry out these roles effectively under very trying circumstances.

It also is important to note that dose–response effects were not always found or sometimes were minimal. The absence of dose–response gradients observed after some time has elapsed since the disaster could reflect recovery processes instead of the absence of dose effects. In their study of adolescents and mothers about 15 months after the 9/11 World Trade Center disaster, Gershoff, Aber, Ware, and Kotler (this issue) found only small effects in one domain (depression) for a dose–response gradient in mental health among the youth in relation to variations in exposure.

There also is some evidence that the dose–response relation may change at very high levels of severe or chronic exposure. For example, results from the study of former child soldiers in Uganda (Klasen et al., this issue) did not show a link between the severity of trauma exposure during their abduction and period of forced service and their postabduction outcomes. It is conceivable that exposure could be so high in some groups that dose no longer is correlated with symptoms because everyone has crossed a threshold that evokes response or overwhelms coping capacity. Beyond this level, differences in vulnerability or protection (moderating influences, such as stress-reactivity or caregiving quality) or differences in the recovery environment may play a role while exposure level may not. Klasen et al. found that posttraumatic outcomes in these child soldiers were associated with lower exposure to adversities after their return, as well as better socioeconomic origins, perceived spiritual support, and less motivation to seek revenge.

The importance of unpacking dose, as well as the nature of the trauma exposure, is underscored by several studies. In their study of young people exposed to war conditions in Bosnia, Layne et al. (this issue) demonstrate that it is feasible and more informative for intervention and theory to disaggregate risk gradients in order to identify differential relations among various risks, promotive factors, or types of trauma exposure and various aspects of outcome. As they note, their results add to a growing body of work focused on differential effects of risks and extreme adversities with an eye toward identifying processes that underlie dose–response patterns and explain how trauma and disaster affect the course of individual functioning and development (Obradović et al., in press). The work of Catani et al. (this issue) highlights the importance of considering the context of the people exposed to disaster, as many of the people of Sri Lanka faced the devastating tidal wave of December 2004, in the context of ongoing war or family violence and economic adversity. Fernando et al. (this issue), in their study of the tsunami survivors of Sri Lanka, argue that it is important to consider the explanatory role of daily stressors as well as disaster exposure.

Betancourt et al. (this issue) describe specifically "toxic" experiences that had lasting and distinctive effects on the child soldiers in this study, including the tragically common experiences of rape and killing others. Young people who perpetrated killing during their time as child soldiers had increasing hostility during the study, whereas those who had experienced rape had more anxiety and hostility, yet also showed more confidence and prosocial attitudes during the course of the longitudinal study. Moreover, they note that female child soldiers who experienced sexual violence face greater stigma than males when they return to the community because of perceptions that these young women are sexually "impure" or "promiscuous." This differential stigma is especially important because Betancourt et al. found that community acceptance was a key protective factor for adjustment of child soldiers after their return to the community.

Results of studies in this issue also emphasize the significance of the adversities in the recovery context or aftermath of disaster. Klasen et al. (this issue), in their study of former child soldiers from Uganda, found that experiences after the children returned were important, with additional exposure to violence (often in the form of domestic or community violence) related to worse outcomes. Kronenberg et al. (this issue) emphasized the role of the postdisaster environment, and particularly the presence of ongoing adversities in the family and community, in their study of students 2–3 years after Hurricane Katrina. The issue of stigma observed for sexually traumatized girls by Betancourt et al. (this issue) represents another form of adversity in the recovery context. However, the significance of the recovery context is not limited to adversity. The special section also underscores the importance of positive features of the recovery context and other protective factors for disaster.

Promotive and Protective Factors

A number of the studies in this section examined variation in the adaptive behavior of the young people studied, often within a resilience framework. Disaster research has played a central role in the history of resilience science, as noted earlier. Studies with a resilience focus typically aim to assess positive as well as negative patterns of adaptation after disaster and also seek to identify the factors or conditions that appear to promote or protect good function during the crisis or recovery period following disaster. Promotive factors predict better outcomes at all levels of risk or adversity (a main effect), whereas protective factors have a greater effect or play a special kind of role when risk or adversity is high (moderating or interaction effect; see Masten, in press).

Moderating effects in response to disaster also can be conceptualized in terms of vulnerability rather than resilience. This distinction can be arbitrary in that it is usually unclear whether the attribute is operating to worsen or improve the outcome, or both. However, when a group of individuals with a particular attribute appear to be particularly susceptible to negative effects of adversity, that attribute is typically described as a vulnerability factor that exacerbates risk. In their commentary in the special section, Peek and Stough (this issue) discuss the vulnerability of children with disabilities in relation to disaster, and concomitantly the vulnerability of communities that do not prepare adequately for meeting the needs of such children during a disaster. Although data are scarce on risk and protective factors for children with disabilities and their families who encounter disasters, children with various disabilities may be particularly endangered by threats encountered in disasters because of specific functional difficulties or sensitivities posed by physical impairments or emotional reactivity related to a disability. They may also be more vulnerable due to lack of planning for children with disabilities during and following disasters. Peek and Stough also note that children with disabilities and their families may be more dependent on special educational or community supports that are disrupted by disaster and therefore more dependent on the community recovery. Yet, it is also conceivable that parents of children with disabilities may develop especially effective strategies and systems for protecting their children in response to the challenges of rearing and protecting a vulnerable child.

Disasters are defined in part by the scope of their impact on the lives of those affected and disasters often threaten the most fundamental adaptive systems for human development (Masten & Obradović, 2008). Children would not be expected to fare well if a tsunami kills their parents and no one is available to care for them, or if they suffer a devastating head injury that impairs subsequent learning and cognition. Extreme psychosocial stress also has the potential to undermine brain development and related cognitive skills, such as memory and executive function through biological stress processes. There is considerable interest in the processes by which psychological or physical adversity experiences become embedded in child development, through a variety of pathways, ranging from the effects of elevated cortisol on the developing brain to the effects of maternal deprivation on attachment, emotional security, mastery motivation, the development of self-regulation, and later relationships (Feder, Nestler, & Charney, 2009; Gunnar & Herrera, in press; Shonkoff et al., 2009).

Several of the articles in the special section address questions on resilience. Generally, the results are consistent with the broader literature on resilience in young people (Luthar, 2006; Masten, 2001, 2007, in press). Kithakye et al. (this issue), in one of the few studies with data on predisaster adjustment, found that self-regulation skills in preschoolers were associated with prosocial behavior in general and had a moderating effect on the relation of exposure severity with prosocial outcomes. The interaction pattern was consistent with other findings in the resilience literature suggesting a protective role of self-regulation skills (Masten, 2007). As indicated previously, community acceptance was important for resilience observed over time in child soldiers by Betancourt et al. (this issue), corroborating other reports on recovery of child soldiers (Boothby, Crawford, & Halperin, 2006). Klasen et al. (this issue) found posttraumatic resilience in former Ugandan child soldiers was associated with fewer guilty cognitions, less desire for revenge, better socioeconomic situation in the family, and greater perceived spiritual support.

In one of the most innovative studies in the special section, Vigil et al. (this issue) examined the potential interacting role of two biological systems—hypothalamic-pituitary-adrenal axis (assessed indirectly by salivary cortisol) and sympathetic nervous system (SNS, assessed indirectly by salivary alpha-amylase)—in relation to function after disaster. Their results are consistent with the possibility that a combination of high cortisol and SNS activity is associated with resilience.

The role of schools in the recovery environment for children has been widely reported in the resilience literature, particularly for war and disaster (Masten & Obradović, 2008), and this perspective is corroborated in the special section. Prompt reestablishment of schooling was one of the most highly endorsed best practices emerging from the consensus study based on the expertise of humanitarian agency leaders with extensive disaster experience (Ager et al., this issue). This theme is also emphasized by Kronenberg et al. (this issue) in the aftermath of Katrina and Betancourt et al. (this issue) in the context of war in Sierra Leone. In the Kronenberg et al. study, schools played a key role in the rebuilding of the community and supporting recovery. In the latter case, staying in school was associated with improved prosocial attitudes and behaviors.

Results also reflect the rising interest in posttraumatic growth in the aftermath of trauma and disaster (see Bonanno, 2004; Kessler, Galea, Jones, & Parker, 2006; Masten & Obradović, 2008; Pat-Horenczyk & Brom, 2007). While the developmental meaning and significance of "better" function during or after disaster remains uncertain, there is growing attention to this kind of phenomenon among young people and adults. In most situations, pretrauma functioning is unknown; therefore, it is unclear how to distinguish normal growth and development from posttrauma growth, and the meaning of better functioning and its long-term possible cost for a child is unknown. The study by Kilmer and Gil-Rivas (this issue) addressed the complex questions of posttraumatic growth in children. While the findings from the Kilmer and Gil-Rivas study are preliminary (and, typical of most disaster studies, did not include predisaster data), these authors suggest the potential benefit of working with children to support relevant competencies and cognitive processes that may foster posttraumatic growth. Their observation that rumination and distressing thoughts were associated with posttraumatic growth raises the intriguing possibility that discomfort in combination with reflective processes could lead to positive changes in the aftermath of trauma.

Gender and Age Differences

The literature on disaster exposure and response in children and adolescents presents a complex picture of gender and age effects, and the studies of this special section do as well. Numerous methodological issues arise in the interpretation of both gender and age effects. Parents and teachers typically are the informants for young children, whereas adolescents often self-report on their own symptoms or well-being, which confounds response with the respondent and most likely gender of the informant with gender of target as women are more likely than men to be the informants for young children. Mothers, for example, may report more of some symptoms in children than objective observers might report and different symptoms than a child himself or herself was able to report. Similarly, when female adolescents report more symptoms than adolescent males, it is not clear whether they experience more symptoms or simply are more willing to admit them.

Following disasters, it is often difficult to find a comparable comparison group, limited measures are available with norm-referenced data on the affected population, and there is rarely any predisaster assessment on the study sample. This situation makes it difficult to know if reported gender or age differences observed among the disaster-exposed group differ from what one might have found in nonexposed young people.

Disaster and trauma studies often find that females report more symptoms (Tolin & Foa, 2006). However, female adolescents and adults generally report or disclose more symptoms of distress, regardless of whether they have experienced trauma (Crick & Zahn-Waxler, 2003). In the Kronenberg et al. (this issue) study following Katrina, female students (4th through 12th grade) reported more depression and trauma symptoms than males, although these investigators noted that it is difficult to know whether these gender differences reflect differential reporting or experiencing of these symptoms. Moreover, without a normative or nonexposed reference group, it is difficult to discern if initial post-Katrina scores reflect elevated symptom levels, although the subsequent decline suggested that this might have been the case. The study by Vigil et al. (this issue) was one of the few to compare a disaster-exposed group (adolescents who experienced Katrina) to a comparable group of nonexposed young people (of comparable sociodemographic background). Results were complex in that Katrina-exposed females appeared to report particularly high symptoms of depression while Katrina-exposed males reported particularly low levels of aggression.

In war and disaster, it also is difficult to sort out the meaning of gender differences even when they are found, because the experiences of males and females may differ in significant ways and the cultural meaning of the experiences may also differ by gender (see Bal, 2008; Barber, 2008; Norris, Perilla, Ibañez, & Murphy, 2001; Pfefferbaum, 1997). As noted earlier, Betancourt et al. (this issue) found that female child soldiers reported more rape experiences than the male child soldiers and that sexual violence held greater stigma for females in the recovery community context.

In the disaster literature, differential vulnerabilities and protective factors have been noted in relation to age for some time (Masten, Best, & Garmezy, 1990). Younger children have been viewed as more vulnerable to the loss or declines in quality of caregiving because of their dependence on care. Young children, on the other hand, are protected in some ways by their lack of exposure to and understanding of disaster as it unfolds, especially when their environment remains relatively stable with support from their families (Osofsky, 2004). Adolescents are viewed as at greater risk of high exposure because of their place in the world, their friends who may have been exposed, and their greater awareness of what is happening and its future significance. Older children and adolescents also are at higher risk of certain dangers (e.g., forced labor, rape, military service). Conversely, older youth have better problem-solving skills, more coping capacity, more social support outside the family, and more capacity to survive on their own than younger children. Thus, the vulnerability and capacity for resilience change over the course of development and also vary with the circumstances of the individual in a disaster.

Age differences in exposure, experiences during and after disaster, and adjustment following disaster were found in several studies in this special section, although the findings are not consistent. Exposure to lifetime disaster was generally higher among older children in the epidemiological survey by Becker-Blease et al. (this issue). Klasen et al. (this issue) observed more trauma and symptoms among the older of the former child soldiers in Uganda, whereas Betancourt et al. (this issue) did not find comparable effects in their study of child soldiers from the conflict in Sierra Leone. Age was unrelated in the latter study to most outcomes, except that older returning soldiers in the Betancourt et al. study experienced less family acceptance than younger children, perhaps because older children evoked less sympathy or more fear. Kronenberg et al. (this issue) found that the younger students (ages 9–11) reported more depression and posttraumatic stress disorder symptoms.

Given the interplay among exposure, development, and individual differences, it is a complex matter to sort out the meaning of observed age-related differences, as noted by Layne et al. (this issue) in their discussion. Indeed, in many respects, the empirical evidence on disaster in relation to development is sparse. Despite numerous signs of progress on multiple fronts in the research on children in disasters, nicely reflected in this collection of articles, developmentally informative data remain limited.

Conclusions

Implications for Research

The special section highlights the challenges, progress, and gaps in research on disaster and child development. Formidable obstacles have impaired progress. These range from the inherent challenges of conducting research under disaster-affected conditions to obtaining rapid funding, especially for those researchers who reside in the disaster-affected areas. However, there is also a profound shortage of suitable standardized and culturally appropriate measures in many of the regions where disasters occur, reflecting a much broader issue in developmental science. There are many more studies and validated measures for developed than developing regions and dominant cultural groups compared with minority groups (Quintana et al., 2006). Building a broader science of child development across cultures and regions would be extremely helpful to research in many domains, and it is critically important for disaster research.

Longitudinal data are scarce, particularly with regard to studies with predisaster baselines, despite the need for information on what may be most helpful to whom and when after disaster. Greater attention may need to be directed toward building national and international supports and structures for disaster research, including technical support and collaborations among teams of developmental scientists, humanitarian service providers, and local leaders or disaster responders.

There continues to be very little attention to developmental issues in disaster research beyond the most basic role of age. Research is needed on the role of developmental timing for exposure, vulnerabilities and protective influences, and patterns of response over the near term and long term. In addition, there is a great need for more developmentally informed and informative research into the effectiveness of prevention and recovery strategies for disaster-affected children and adolescents, especially with regard to considerations of development, gender and cultural differences, and the nature of the disaster exposure. Layne et al. (this issue) provide a compelling argument for research that attempts to unpack the complex interplay among development, trauma exposure, resources, and protective or vulnerability processes, particularly in order to inform intervention. They assert that a more differentiated understanding of ''who is at risk for what outcomes via which pathways of influence'' (p. 1072) will inform evidence-based clinical decisions. Developmental considerations need to be at the center of the unpacking mission.

Implications for Disaster Preparation and Response

The existing literature on disasters and child development and the broad array of articles in this special section provide important information not only for developmental science but also for efforts to address the needs of children and youth in the context of disaster. While there are many gaps in the research, disasters continue to unfold worldwide, and it is reasonable to consider the implications of current findings from the special section and earlier work for efforts to help the many young victims of disaster. There is some consistency in the findings that may afford helpful guidance in preparing for disaster and promoting resilience in its wake.

By definition, it is not possible to be fully ''prepared'' for a disaster. Nonetheless, the findings to date, including data from articles in this section, suggest that communities can plan and prepare to support the mobilization of family and community resources to protect children and promote resilience in situations of overwhelming adversity. The lessons for preventive intervention from the growing body of research on disasters and children, as highlighted in the special section, can be summarized in terms of developmental guidelines as follows (see also Hobfoll et al., 2007; Masten & Obradović, 2008; Norris, Steven, Pfefferbaum, Wyche, & Pfefferbaum, 2008; Norris & Stevens, 2007; Osofsky et al., 2007; Pine et al., 2005).

1. Protect and restore the secure base of attachment relationships as soon as feasible. Prepare for evacuations and relocations that include keeping children together with their caregivers. Reunite children and adults who have attachment bonds if they have to be separated. Provide nurturing caregivers for children who have lost their caregivers.
2. Train first responders in the range of developmental responses to trauma that can be expected for children of different ages.
3. Remember that first responders for children include parents, teachers, and day-care providers in addition to emergency responders.
4. Support normalizing routines, activities, and contexts for children after disasters, including opportunities for them to play and learn, and the restoration of functional schools and other community organizations that serve children and their families.
5. Attend to community resilience and the function of cultural and community practices that support families and their children, including support for spiritual practices.
6. Support and restore meaningful relationships and opportunities to be effective in play, school, work, or recovery activities. Such activities may nurture hope, meaning, and a sense of agency, both in adults who care for children and among older children and adolescents themselves.

Perhaps the most important role for developmental scientists in disaster response, however, is for them to engage more fully in the process of building and applying knowledge. Scientists with developmental knowledge rarely are included in decision making related to recovery and rebuilding following disasters, while scientists, in turn, may not reach out to help as effectively as possible. In the United States, the National Child Traumatic Stress Network (Pynoos et al., 2008) can play an important role in brokering this bidirectional process for disaster planning and response. Internationally, Ager et al. (this issue) have articulated the requirements for developmental scientists to contribute to the humanitarian efforts on behalf of children in disasters. These include research engagement in more diverse cultural settings around the world, including those in crisis, and more effective translational efforts to communicate their findings to practitioners and policymakers.

The work of the scientists who have contributed to this special section on disasters and child development illustrates what can be done under extraordinarily challenging conditions. At the same time, the special section also underscores the limits of present knowledge and potential for further research contributions by developmental scientists in this area. Developmental scholars have a vital role to play in shaping future science and its applications to reduce the negative effects of disaster on human development and promote adaptive responses and recovery in young people, their families, communities, and societies.

Disasters, Victimization, and Children's Mental Health

Kathryn A. Becker-Blease
Oregon State University

Heather A. Turner and
David Finkelhor
University of New Hampshire

In a representative sample of 2,030 U.S. children aged 2–17, 13.9% report lifetime exposure to disaster, and 4.1% report experiencing a disaster in the past year. Disaster exposure was associated with some forms of victimization and adversity. Victimization was associated with depression among 2- to 9-year-old disaster survivors, and with depression and aggression among 10- to 17-year-old disaster survivors. Children exposed to either victimization only or both disaster and victimization had worse mental health compared to those who experienced neither. More research into the prevalence and effects of disasters and other stressful events among children is needed to better understand the interactive risks for and effects of multiple forms of trauma.

Disasters are relatively common events that disrupt children's basic needs including access to food, water, shelter, and primary caregivers. Much of what we know about disasters and children comes from samples of children exposed to a relatively few, large-scale disasters rather than from representative samples across the population (e.g., Centers for Disease Control, 2005; Landrigan et al., 2008; see Norris et al., 2002, for a review). In addition, we know little about how exposure to disasters is associated with exposure to other kinds of stressful events. In this study, we investigate the prevalence and effects of disasters and other stressful events in a representative sample of U.S. children.

Definitions

In this article, we use the term *disaster* to refer to one-time or ongoing events of human or natural cause that lead groups of people to experience stressors including the threat of death, bereavement, disrupted social support systems, and insecurity of basic human needs such as food, water, housing, and access to close family members. We use the term *victimization* to refer to "harms that occur to individuals because other *human actors* behaving in ways that *violate social norms*" (italics in original, Finkelhor & Kendall-Tackett, 1997, p. 2). Victimization includes maltreatment, sexual and physical abuse, neglect, exposure to domestic violence, and other crimes such as theft and peer and sibling physical assault. Finally, we use the term *adversity* to refer to other (nonvictimization, nondisaster) events that have been associated with poorer mental health, including having an incarcerated or substance-abusing parent. Disasters, victimization, and other adverse events are interrelated in complex ways. Exposure to any one type of event could put children at risk to experience other types of events, or affect how children respond if and when they experience another kind of event. Additional environmental and genetic factors could be implicated both in risk of exposure and for outcomes following exposure to any of these events.

Disasters

General population studies indicate that many people in the United States experience disasters each year. Adults self-report a lifetime prevalence rate of 11%–30% (Briere & Elliott, 2000; Goldberg &

For the purposes of compliance with Section 507 of PL 104-208 (the "Stevens Amendment"), readers are advised that 100% of the funds for this program are derived from federal sources (this project was supported by Grants 1999-JP-FX-1101 and 2002-JW-BX-0002 awarded by the Office of Juvenile Justice and Delinquency Prevention, Office of Justice Programs, U.S. Department of Justice). The total amount of federal funding involved is $584,549. Points of view or opinions in this document are those of the author and do not necessarily represent the official position or policies of the U.S. Department of Justice. The authors wish to thank Richard Ormrod for help with data management, and John Boyle and Patricia Vanderwolf for help in data collection.

Freyd, 2006; Green & Solomon, 1995; Norris et al., 2002) depending in part whether disaster is defined exclusively as natural disasters, or also includes human-caused incidents. To the best of our knowledge, this study is the first to obtain a national prevalence estimate for disaster exposure among children in the United States.

Numerous researchers have examined children's reactions to large-scale disasters worldwide. From these studies, we know that disasters are implicated in a range of physical effects, including traumatic brain injury, low birth weight, and respiratory, musculoskeletal, and other physical symptoms (Dirkzwager, Kerssens, & Yzermans, 2006; Keenan, Marshall, Nocera, & Runyan, 2004; Landrigan et al., 2008; Rath et al., 2007). Psychological sequalae include posttraumatic stress symptoms, depression, anxiety, behavior problems, sleep problems, and learning problems (Norris et al., 2002; Stein et al., 2004; Weems et al., 2007). Based on a review of many studies, Norris et al. (2002) concluded that school-age children are more likely than adults to experience severe impairment following disasters.

A few studies point to differential effects of disasters for adolescents compared to younger children. Increased aggression and enuresis among 2- to 9-year-olds have been reported 6 months after a flood (Durkin, Khan, Davidson, Zaman, & Stein, 1993) and preschoolers demonstrate increased fear of storms, concern for others, and other signs of disaster experience in their play up to 1 year following a hurricane (Saylor, Swenson, & Powell, 1992). Other studies of children who were under age 5 at the time of exposure to nuclear accidents show few long-term effects (Bromet et al., 2000; Cornely & Bromet, 1986). Dirkzwager et al. (2006) reported that children aged 4–12 reported increased sleep problems relative to controls, whereas adolescents aged 13–18 reported increased anxiety symptoms compared to controls. Green et al. (1991) studied children who experienced a dam collapse 2 years prior. They report that children aged 2–8 reported fewer posttraumatic stress disorder symptoms than children aged 9–15. Most symptoms had disappeared 17 years after the disaster, but some new symptoms (suicidal ideation and substance abuse) arose as participants aged (Green et al., 1994). Based on the available evidence, young children have been found to show less severe symptoms of shorter duration than older children and adolescents, but not enough data are available to speak definitively about age effects among children, particularly for those under 5.

Victimization

Studies investigating the effects of various forms of victimization (Finkelhor, Ormrod, & Turner, 2007) and adverse childhood experiences (Dong et al., 2004) have demonstrated that many people who experience one type of stressful event are likely to experience other types. When multiple stressful events are not considered simultaneously, consequences of multiple events may be attributed to the single event that is the focus of study. There is a particular risk of this effect with disaster research because most disaster research seeks samples after a particular event for the specific purpose of determining the effects of that one particular event. The data set used in this study allows us to estimate the effects of a wide range of stressful events, including disasters.

Disasters, Victimization, and Other Adversity

It is easy to imagine that risk for some stressful events puts children at risk for similar types of events. Poverty, parenting capacity, social support, and many other environmental factors may lead to the empirical evidence demonstrating associations among types of maltreatment and victimization. Why would we predict an association between exposure to victimization and disasters? At least two mechanisms could result in an association between disasters and other stressful events. First, the stress of the disaster may impair parents' ability to care for their children. As reviewed by Norris et al. (2002), adults exposed to disaster may experience sleep disturbance, a worsening of mental health symptoms, reduced social support, and increased use of alcohol following disasters. Further, several studies have pointed to increases in child abuse following natural disasters, although this finding is not universal (Curtis, Miller, & Berry, 2000; Keenan et al., 2004).

It is also possible that some of the same risk factors are associated with both disasters and victimization. In the geography and community development literature, vulnerability to disaster is conceptualized as the interaction between risk of disaster exposure and the ability to prepare for and respond to disasters (Cutter & Finch, 2008; Masozeraa, Bailey, & Kerchner, 2007). For the purposes of this article, we are mainly concerned with risk of exposure, but the overlap of concepts is relevant to our definition of *disaster*, as well as our survey respondents' definitions. People who experience an ice storm for which both they and their community are prepared are less likely to self-report disaster exposure than another person who survived a storm that resulted in injuries and death. In another example, a homeowner living in a well-maintained home is at less risk for experiencing a major fire than is someone living in an apartment complex with inadequate fire alarms and escape routes. For these reasons and others, socioeconomic status (SES), urbanity, and race and ethnicity are persistent predictors of vulnerability to disaster (Cutter & Finch, 2008). These same factors are consistent predictors of exposure to victimization (Finkelhor et al., 2007; Stein, Jaycox, Kataoka, Rhodes, & Vestal, 2003). Likewise, some of the same factors that underlie risk of disaster exposure, also put children at risk for poorer mental health outcomes. Parents who have more resources are not only more able to locate safe shelter out of the way of a natural disaster but also in a better position to help children cope with the event and obtain professional mental health services if required.

Research Questions and Hypotheses

1. How many children are affected by disasters in the United States?
2. Is risk for disaster exposure associated with risk for exposure to other stressful events? We hypothesized that risk for disaster would be associated with risk of physical abuse, exposure to domestic and community violence, and other adversity. We made no hypotheses about the causality of this association.
3. To what extent is victimization history associated with mental health symptoms among disaster victims? We hypothesized that among disaster victims, victimization would be a significant predictor of mental health.
4. How do mental health symptoms compare for children who have experienced disasters, victimization, both disaster and victimization events, and neither disaster nor victimization events? We hypothesized that those who had experienced neither a disaster nor victimization would report the least mental health symptoms, those who had experienced both would report the most symptoms, and those who experienced either a disaster or victimization would have intermediate scores.

Method

Participants

This research is based on data from the Developmental Victimization Survey (DVS), designed to obtain 1-year incidence estimates of a comprehensive range of childhood victimizations across gender, race, and developmental stage. The survey, conducted between December 2002 and February 2003, assessed the experiences of a nationally representative sample of 2,030 children aged 2–17 living in the contiguous United States. The survey was conducted in English, and 1% of those contacted were unable to complete the survey due to a language barrier. The interviews with parents and youth were conducted over the phone by the employees of an experienced survey research firm specially trained to talk with children and parents. Telephone interviewing is a cost-effective methodology (Weeks, Kulka, Lessler, & Whitmore, 1983) that has been demonstrated to be comparable in reliability and validity with in-person interviews, even for sensitive topics (Bajos, Spira, Ducot, & Messiah, 1992; Bermack, 1989; Czaja, 1987; Marin & Marin, 1989). The methodology is also used to interview youth in the U.S. Department of Justice's National Crime Victimization Survey (Bureau of Justice Statistics, various years) and in a variety of other epidemiological studies of youth concerning violence exposure (Hausman, Spivak, Prothrow-Stith, & Roeber, 1992).

The sample selection procedures were based on a list-assisted random digit dial telephone survey design. This design increases the rate of contacting households with children aged 2–17 while decreasing the rate of dialing business and nonworking numbers. Experimental studies have found this design to decrease standard errors relative to the standard Mitofsky–Waksberg (Waksberg, 1978) method while producing samples with similar demographic profiles (Brick, Waksberg, Kulp, & Starer, 1995; Lund & Wright, 1994).

A short interview was conducted with an adult caregiver (usually a parent) to obtain family demographic information. Because the questions in the survey are of a sensitive nature, interviewers explained the study honestly and carefully up front. Care was taken to not refer to the study as a "crime" study, as many victims of crimes do not label their experiences as a *crime*. Instead, children's "safety" was emphasized.

Specifically, parents of 2- to 9-year-olds were told:

> This study is being conducted by the [Name of University] to better understand problems facing children today. For this study, we will be interviewing 2000 families across the country to find out about stressful events that happen to some children, and how schools and various agencies may better protect kids from dangerous situations. Your family was selected at random to represent families with children aged 2–17. Your interview will take about 30 minutes. We will be asking you about things that may have happened in your child's school, neighborhood, or home, and about how your child's health has been lately. Some of the questions involve sensitive issues, such as whether your child has ever experienced violence and whether your child has ever experienced unwanted sexual advances.

Parents of 10- to 17-year-olds were told:

> In learning about child safety for children, we would like to get the input of both children and their parents. It is particularly important for us to find out what kinds of situations *kids* consider dangerous, whether they have ever encountered these situations, and what they know about how to avoid or handle these situations . . . We will be asking him/her about things that may have happened in your child's school, neighborhood, or home, and about how your child's health has been lately. . .
>
> Some of the questions involve sensitive issues, such as whether your child has ever experienced violence and whether your child has experienced unwanted sexual advances.

Before beginning the survey, 10- to 17-year-olds were told:

> Your age group (x-year-olds) is part of national sample of 2,000 boys and girls selected completely at random. You will be representing all kids in the United States in your age group. This is an important study because you'll be able to tell us what kinds of dangerous situations kids face these days. What you and the other kids tell us will help us keep kids safe. Your interview will take about 20–30 minutes. We will be asking you about things that may have happened in your school, neighborhood, or home. We'll also ask about how your health has been lately. Some of the questions involve sensitive issues, such as whether you have experienced violence.

One child was randomly selected from all eligible children living in a household by selecting the child with the most recent birthday. If the selected child was 10–17 years old, the main telephone interview was conducted with the child. If the selected child was 2–9 years old, the interview was conducted with the caregiver who "is most familiar with the child's daily routine and experiences." Caregivers were interviewed as proxies for this age group because the ability of children under the age of 10 to be recruited and participate in phone interviews of this nature has not been well established (Hausman et al., 1992; Waksberg, 1978), yet such children are still at an age when parents tend to be well informed about their experiences both at and away from home. In 68% of these caretaker interviews, the caretaker was the biological mother, in 24% the biological father, and in 8% some other relative or caretaker.

Data were collected using a computer-assisted telephone interview system (CATI). The use of CATI minimizes recording errors and provides substantial quality control benefits. For this survey, only interviewers who had extensive experience interviewing children and in addressing sensitive topics were chosen. Interviewers then went through extensive training on the questionnaire and interview protocol.

Up to 13 callbacks were made to select and contact a respondent and up to 25 callbacks were made to complete the interview. Consent was obtained prior to the interview. In the case of a child interview, consent was obtained from both the parent and the child. Respondents were promised complete confidentiality and were paid $10 for their participation. Telephone interviewers screened 7,907 households. Of those, 5,011 households did not have an eligible child, 511 declined to participate, and 350 agreed to participate at another time but were unable to be reached by the end of the study. Of the 2,896 eligible households screened, interviews were completed with 2,035 participants, representing 70.3% of eligible households. The final sample consisted of 1,000 children aged 10–17 and 1,030 caregivers of children aged 2–9.

All procedures were authorized by the Institutional Review Board of the University of New Hampshire. Both universal and targeted interventions were used to assist children who were potentially at risk for abuse, or harm to self or other. All participants were given the phone number to the Girls and Boys Town National Hotline. The U.S. Department of Health and Human Services describes hotline this way:

> The Girls and Boys Town National Hotline is a 24-hour crisis, resource and referral line. Accredited by the American Association of Suicidology, the Hotline has been in operation since 1989 and is staffed by trained counselors who can respond to questions every day of the week, 365 days a year. Approximately 250,000 callers contact the hotline annually to receive help relating to being suicidal, physically or sexually abused, on the run, addicted, threatened by gang violence, fighting with a parent, a parent frustrated by a child, scared of a spouse, or faced with an overwhelming challenge. (Healthfinder.gov, 2008)

Additionally, the CATI system was programmed to flag automatically cases in which a child could have been in danger. Interviewers also flagged cases that presented a concern and provided brief notes that could be used to better understand the situation. Children or parents who disclosed a situation of serious threat or ongoing victimization were recontacted by a clinical member of the research team, trained in telephone crisis counseling, whose responsibility was to stay in contact with the respondent until the situation was resolved or brought to the attention of appropriate authorities. The kinds of concerns varied widely and included depressed children who were seeking treatment, teenagers who were slapped once or twice by a parent, abused children who no longer had contact with the abuser, and adolescents who reported ''pressure'' to have sex from a romantic partner. In no case did it become necessary for the phone counselor to report suspected abuse of a child.

Measures

Demographic variables. All demographic information was obtained from the parent during the initial parent interview. Parents provided the child's age (in years), race and ethnicity (coded into four groups: White non-Hispanic, Black non-Hispanic, Hispanic any race, or Other Race non-Hispanic) and current family structure (coded into three groups: two biological or adoptive parents, one biological and a married or unmarried partner, or single-parent family). Participants also reported 2002 household income from wages, public assistance and child support (10 categories: $5000 or less through more than $100,000), and the highest education completed (for the parent with the most education, 11 categories: grade school through graduate degree).

Lifetime victimization. Victimization data were collected using the Juvenile Victimization Questionnaire (JVQ; Hamby, Finkelhor, Ormrod, & Turner, 2004). The JVQ was designed to assess a wide range of childhood victimization experiences, across childhood and adolescence. The same questions were used for self-report interviews with 10- to 17-year-olds and parent-report interviews for 2- to 10-year-olds, except for slight wording changes as needed (e.g., ''your child'' substituted for ''you'').

Concerns about the validity of self- and parent-reports take two forms. Some are concerned that respondents may underreport victimization events to avoid culpability, due to stigma, or due to forgetting. Others are concerned that respondents might overreport victimization events, to explain problems in their lives or to assist with child custody claims. It is possible that these motives were present for a small number of respondents, but we do not find systematic evidence of a greater bias toward under- or overreporting for parent-report versus self-report data (Finkelhor, Hamby, Ormrod, & Turner, 2005). Previous analyses have also demonstrated good respondent comprehension, construct validity, and test–retest reliability for JVQ items (Finkelhor et al., 2005). Researchers who have looked at this issue have found that while there is likely to be some underreporting in parent and self-reports, these reports are likely to be more valid than official reports that greatly underestimate victimization experiences (Hardt & Rutter, 2004; Kendall-Tackett & Becker-Blease, 2004; Straus, 1992).

The analyses presented in this article are based on 20 items covering four domains of victimization—sexual assault, maltreatment, witnessing family violence, other major violence—the screener questions for each module are available in Appendix A of Turner, Finkelhor, and Ormrod (2006). The complete text of the questions is available in Hamby et al. (2004). Participants were asked about each event in the past year. If no event was reported for the past year, participants were asked if the event had ever happened in their lifetime. From these data, we calculated the number of types of events reported across participants' lifetimes.

Nonvictimization adversity. The nonvictimization adversity module of the JVQ includes 15 stressful events and chronic stressors, including an item assessing exposure to a disaster. For the purposes of these analyses, we include only the 14 nondisaster items in the adversity score.

Lifetime and past-year disaster exposure. Disaster exposure was measured using the following item, "In your (your child's) whole life, were you (was she or he) ever in a VERY BAD fire, explosion, flood, tornado, hurricane, earthquake or other disaster?" For those respondents who answered yes, follow-up questions assessed how many times, whether the most recent event happened in the past year, what type of disaster was experienced, the child's age at the time of the disaster, and if the child knew anyone who was injured in the disaster.

Current mental health symptoms. Mental health symptoms were measured using the anxiety, depression, and aggression subscales of the Trauma Symptom Checklist for Young Children (Briere et al., 2001; for children aged 2–9) and the Trauma Symptom Checklist for Children (Briere, 1996; for children aged 10–17). Both instruments assess reactions to a wide range of nonspecific stressful events across several domains. Participants report on how frequently they (or, for parents of 2- to 9-year-olds, their child) had experienced a list of behaviors, thoughts and feelings on a 4-point scale (0 = *not at all*, 4 = *very often*) over the past month. In this sample, approximately 5% of respondents scored in the subclinical or clinical range for anxiety, depression, or aggression. Because of the small number of extreme scores, we used continuous measures of mental health symptoms in our analyses.

Analysis Plan

We used 2002 Census estimates (U.S. Census Bureau, 2000) to apply poststratification weights to adjust for the underrepresentation of Blacks and Hispanics in our sample relative to the national population. Weights also adjusted for the probability of selection due to the number of children in the household and the fact that only one child per household was selected to participate. Unless otherwise noted, analyses were conducted with weighted data. Due to the potential for method variance between the younger (parent report) and older (self-report) groups, data for the younger and older groups were analyzed separately. Within each group, age was positively associated with disaster and victimization exposure. Thus, where indicated, age is included as a covariate.

In tests of group differences, children who had experienced any incident within a victimization domain (sexual assault, maltreatment, witness domestic violence, other major violence) were included in that category of victimization and in the category of "any victimization."

For Hypothesis 1, we ran frequency counts for children reporting disaster and victimization experiences.

To test for associations between experiencing a disaster and victimization (Hypothesis 2), we conducted chi-square analyses to examine associations between lifetime disaster, victimization, adversity experience. We also used partial correlation to test for associations among disaster exposure, adversity, any victimization, sexual victimization, maltreatment, domestic violence, and other major violence, controlling for age.

For Hypothesis 3, we ran regression analyses with victimization and control variables predicting mental health symptoms among participants who reported experiencing a disaster.

For Hypothesis 4, we used analysis of covariance (ANCOVA) to compare mental health symptoms among four groups: no disaster or victimization, disaster only, victimization only, and both disaster and victimization, controlling for demographic factors. Bonferroni-corrected contrasts were used to identify significant differences among the four groups.

Regression analyses were used to identify predictors of mental health symptoms when group differences indicated greater symptoms among disaster victims relative to peers who did not experience disaster. In these analyses, victimization was calculating by summing the number of reported incidents across the four domains assessed. The theoretical range was 0–20 and participants reported between 0 and 12 incidents ($M = 0.82$, $SD = 1.52$). Adversity scores were obtained by giving a score of 1 for each type of adversity that the child had ever experienced and summing to form a continuous score. Race and ethnicity was coded into four groups: White and non-Hispanic, Black and non-Hispanic, Other Race and non-Hispanic, and Hispanic. Family structure was coded into three groups: single parent, stepparent household, and two biological or adoptive parents. To construct an index of SES, income and parental education scores were separately standardized, summed and then restandardized. When either income or education data were missing, the SES score is based on the variable available.

Results

Table 1 shows demographic variables for the sample.

How Many Children Are Affected by Disasters in the United States?

Based on analyses with weighted data, 281 or 13.9% of children and teens had been in a disaster during their lifetime, and 4.1% of the sample experienced a disaster in the past year. By comparison, 13.7% reported sexual victimization, 20.0% reported maltreatment, 10.6% reported witnessing family violence, and 17.3% reported witnessing other major violence within their lifetimes. In total, 36.4% reported experiencing at least one victimization incident. Age at the time of disaster ranged from < 1 year old through 16 years old.

Of those who had experienced a disaster in their lifetime, 24.6% reported experiencing more than one. With respect to the most recent event, 12.8% had been in a fire, 26.7% in a tornado, 14.6% in a fire, 24.2% in a hurricane, and 17.8% in an earthquake. Eight participants indicated other disasters including bad ice and wind storms, the Oklahoma

Household income (per year)[e]				
Under $20,000	98	9.5	100	10.0
$20,000–$50,000	376	36.5	317	31.7
More than $50,000	464	45.0	469	46.9

Note. Except for region of the United States, all demographic data were provided by the caregiver.
[a] Respondents indicated "unknown" race/ethnicity information for 13 children aged 2–9 and 9 children aged 10–17. [b] U.S. regions correspond to Census data and were derived from telephone area codes. [c] Metropolitan areas were defined as follows: rural = population < 20,000; town = 20,000–100,000; large city = population of 300,000 or more. Data were not available for 9 children aged 2–9 and 9 children aged 10–17. [d] Highest parent education is the highest level of education obtained by any parent in the home and was reported by the caregiver. Data were not available for the caregivers of 1 child aged 2–9. [e] Caregivers declined to provide household income information for 92 children aged 2–9 and 114 children aged 10–17.

City bombing, and World Trade Center attacks. Nine participants (.4%) reported being injured in the disaster.

Is Risk for Disaster Exposure Associated With Risk for Exposure to Other Stressful Events?

Table 2 presents the percentage of participants who experienced victimization and other adversity, by disaster exposure history and age group. These results do not control for age within each age group.

Partial correlation was used to examine relations between lifetime disaster exposure and history of victimization and adversity, controlling for age. Contrary to Hypothesis 2, for 2- to 9-year-olds, no correlation was found between lifetime disaster experience and lifetime sexual victimization ($r = .03$, $p = .31$), witnessing domestic violence ($r = .02$, $p = .45$), other major violence ($r = -.03$, $p = .30$), or any kind of victimization ($r = .02$, $p = .53$) when age was controlled. However, experiencing a lifetime disaster was positively associated with experiencing maltreatment ($r = .06$, $p = .04$) and adversity ($r = .08$, $p = .1$) with age controlled.

Supporting Hypothesis 2, among 10- to 17-year-olds, correlation analyses controlling for age showed a positive relation between lifetime disaster exposure and lifetime sexual victimization ($r = .86$, $p < .001$), maltreatment ($r = .29$, $p < .001$), and adversity ($r = .13$, $p < .001$). There was no correlation with witnessing domestic violence ($r = -.002$, $p = .48$). Contrary to predictions, a negative relation emerged between lifetime disaster exposure and major violence ($r = -.15$, $p < .001$) and any kind of victimization ($r = -.16$, $p < .001$) with age controlled.

Is Victimization Associated With Mental Health Among Lifetime Disaster Victims?

Controlling for sex, race and ethnicity, parent makeup, age, and SES, victimization but not adversity was associated with mental health symptoms (see Table 3). Specifically, among 2- to 9-year-olds, victimization predicted depression scores. Among 10- to 17-year-olds, victimization predicted depression and anger/aggression scores.

How Do Mental Health Symptoms Compare for Children Who Have Experienced Disasters, Victimization, Both Disaster and Victimization Events, and Neither Disaster Nor Victimization Events?

As shown in Table 4, among 2- to 9-year-olds, lifetime disaster and victimization exposure was significantly associated with anxiety, depression, and aggression in a model that included sex, age, race and ethnicity, parent makeup, and SES. Marginal means and Bonferroni-corrected contrasts comparing participants who experienced neither disaster nor victimization, disaster only, victimization only, or both disaster and victimization are presented in Table 5 and Figure 1. Those who experienced victimization only had higher scores than those who experienced neither disaster nor victimization or disaster only. Two- to 9-year-olds who experienced disaster only had unexpectedly low scores that did not differ significantly from those who had experienced neither a disaster nor victimization.

Table 2

Estimated Percent of Disaster Victims Who Also Experienced Victimization and Other Adversity

	Sex victim	Maltreatment	Witness family violence	Major violence	Any victim	Adversity
2- to 9-year-olds (*n*)						
Disaster victims (75)	2.7	8.0	6.7	13.3	24	18.7_a
No disaster reported (933)	4.2	15.1	9.4	8.9	25.6	64.3_a
10- to 17-year-olds (*n*)						
Disaster victims (207)	30.4_b	35.7_c	14.0	39.1_d	64.7_e	99.0
No disaster reported (809)	21.2_b	22.6_c	11.4	21.8_d	42.6_e	88.9

Note. Chi-square tests revealed statistically significant association between those cells marked with identical subscripts.
${}_a\chi^2(1, N = 1{,}008) = 8.91$, $p = .002$. ${}_b\chi^2(1, N = 1{,}014) = 7.80$, $p = .01$. ${}_c\chi^2(1, N = 1{,}014) = 15.28$, $p < .001$. ${}_d\chi^2(1, N = 1{,}014) = 26.68$, $p < .001$. ${}_e\chi^2(1, N = 1{,}014) = 32.90$, $p < .001$.
Because data are weighted, observed cell counts are not whole integers. Rounding within cells resulted in $n = 282$ disaster victims for the sexual victimization and witnessing family violence. For maltreatment, major violence, and any victimization analyses, disaster victims $n = 281$. Four participants indicated they were "not sure" if the child/teen had been in a disaster and are not included in this analysis.

$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

Also shown in Table 5, as well as in Figure 2, are mental health scores by disaster and victimization group among 10- to 17-year-olds. In interpreting Figure 2, it is important to consider the variance in standard errors of the estimated marginal means. For each mental health subscale, disaster survivors' standard errors of the estimated marginal mean symptom score are greater than for the other three groups. This contributes to the fact that contrasts between scores for disaster survivors and the other three groups in many cases failed to reach traditional levels of significance. The mean mental health symptoms scores for lifetime disaster only survivors were in the predicted direction, that is, higher than those who had experienced neither a victimization nor a disaster, and lower than those who had experienced either victimization only or victimization and disaster. Consistent with Hypothesis 4, 10- to 17-year-olds who experienced neither a disaster nor victimization had the lowest anxiety, depression, and aggression scores.

Discussion

To the best of our knowledge, this article provides the first prevalence and incidence estimate of disasters in a nationally representative sample of U.S.

Table 5

Estimated Marginal Means for Mental Health Scores by Age and Disaster and Victimization History

	Anxiety		Depression		Anger/aggression	
	Estimated marginal mean	Standard error	Estimated marginal mean	Standard error	Estimated marginal mean	Standard error
2- to 9-year-olds (*n*)						
Neither (614)	2.73_{a}	0.21	1.81_{cd}	0.13	2.80_{h}	0.22
Victimization only (217)	4.00_{ab}	0.25	2.97_{cef}	0.16	5.44_{hi}	0.27
Disaster only (54)	2.59_{b}	0.44	1.43_{eg}	0.28	2.63_{i}	0.48
Both (217)	4.64_{b}	0.85	4.42_{dfg}	0.54	3.91	0.92
10- to 17-year-olds (*n*)						
Neither (409)	1.92_{jkl}	0.24	1.70_{mno}	0.25	2.22_{pqr}	0.29
Victimization only (308)	4.66_{j}	0.24	4.40_{m}	0.25	5.44_{p}	0.29
Disaster only (59)	2.88_{k}	0.48	3.13_{n}	0.49	4.63_{q}	0.57

Note. Bonferroni-corrected contrasts indicated that means with identical subscripts were significantly different ($p < .05$) from each other.

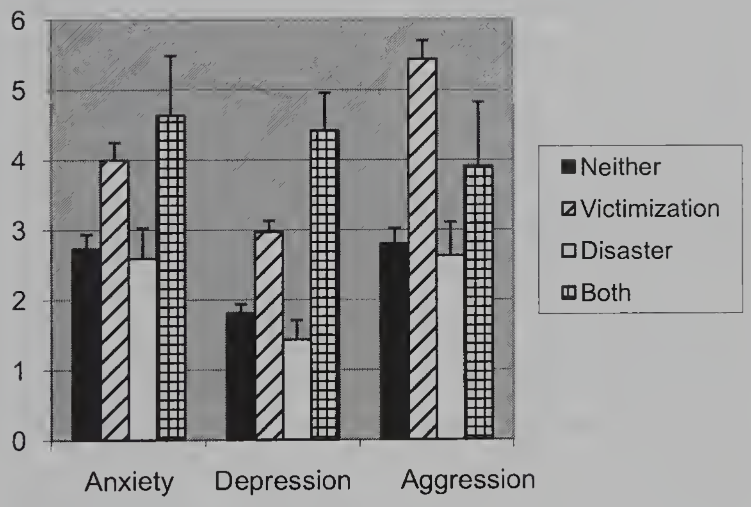

Figure 1. Marginal means for 2- to 9-year-olds' mental health symptoms by victimization and disaster exposure.

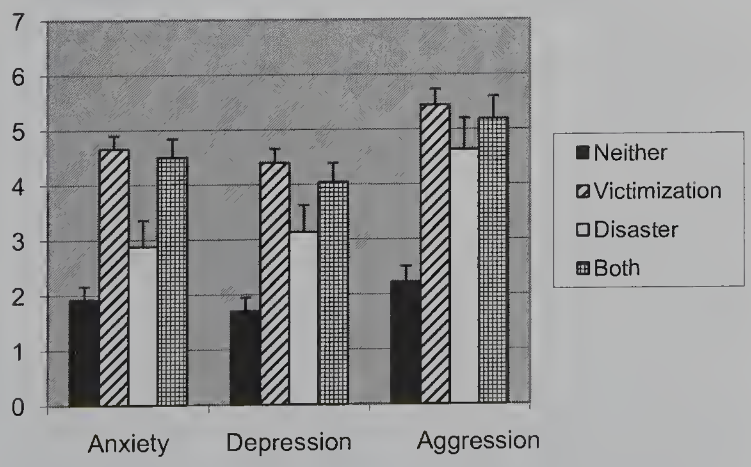

Figure 2. Marginal means for 10- to 17-year-olds' mental health symptoms by victimization and disaster exposure.

children. While the number of studies documenting the effects of disasters on children is increasing, it is important to know how many children experience disasters in order to understand the magnitude of the effects of disasters nationwide.

It was surprising that only 2 of 70 past-year disaster victims reported receiving counseling. We had expected more children to have received counseling because disasters tend to be relatively publicly known, nonstigmatized, and elicit community response. Some children may have received counseling following a disaster, but it was not reported because of the wording of our question that asked about counseling ''for emotional or behavioral problems.'' It is quite possible that some participants did not consider disaster-related counseling to be ''for emotional or behavioral problems.''

We found an association between exposure to disasters, maltreatment, and adversity (controlling for age) among both age groups. Risk for disaster exposure shares some risk factors with risk for maltreatment and adversity. It is also possible that disaster exposure increases children's risk for subsequent maltreatment and adversity. Some of the adversities measured could have been directly related to a disaster (e.g., being homeless, knowing someone who died, seeing a dead body). Others are less likely to be related (e.g., being teased about one's appearance).

Regardless of the overlap in exposure to disasters and victimization, mental health professionals would benefit from knowing if previous or concurrent victimization is a significant predictor of mental health among those who have experienced a disaster. We found that this is the case. Among lifetime disasters survivors, victimization history predicted 2- to 9-year-olds' depression scores, and 10- to 17-year-olds' depression and anxiety scores. We lacked the information to know if victimization is associated with children acutely exposed to disaster, but the association between lifetime exposure to disaster and victimization suggests the need for screening for victimization history among young disaster victims when treating mental health symptoms.

Finally, we compared mental health symptoms among children who have experienced disaster only, victimization only, neither disaster nor victimization, or both disaster and victimization. A surprising finding affected the interpretation of the hypothesized effect: Two- to 9-year-olds who experienced both disasters and victimization and 10- to 17-year-olds who experienced disasters only had more variable mental health scores than peers in the other three groups. This effect should be tested in future research. If this result stands, it suggests a need for careful screening to differentiate those children who are at risk for negative mental health outcomes.

The possibility of method bias is introduced by having parents report on behalf of young children while older youth provided self-reports. The decision to use different reporters for younger versus older youth was made to reduce bias that is known to exist when parents are asked to report on their older children's experiences and mental health. Based on the available evidence, this procedure offered the most accurate data available given the subject matter. Nevertheless, we do not have retrospective reports from participants later in life, nor do we have corroborative reports from other sources. Additional clinical measures (e.g., structured clinical interviews) would have yielded additional information about the diagnosis of mental disorders in this sample.

Despite many strengths of this study, there are some limitations to discuss. Because we sampled households with telephones, the sample probably underrepresented low-income and homeless families. We asked about victimization, disaster, and adversity prior to asking about mental health symptoms. It is possible that the sequence of questions led to higher reports of mental health symptoms. On the other hand, youth experiencing depression and anxiety symptoms may have been more likely to recall and report bad events, inflating the association between negative past events and mental health. The retrospective nature of reports could lead to underreporting, especially of sensitive questions about abuse. Because many abuse events are not reported to authorities, we believe self-reports are an important method for collecting these data, but underreporting could have led to underestimating associations between some victimization experiences and mental health. We do not, in these data, have the ability to know the sequence of disaster exposure, victimization, other adversity and onset of mental health symptoms. Longitudinal, prospective data would better address the important question of whether being in a disaster leads to other adversities or even puts children at risk for victimization.

In addition to addressing these limitations, future research may also assess several factors that may well mediate or moderate the association between disaster exposure, victimization, and mental health symptoms, such as level of fear, loss of property, homelessness, lack of food and water, and separation from caregivers. In fact, some of these factors may be more related to certain types of posttraumatic stress disorder or other mental health symptoms than others (Briere & Elliott, 2000). Outcomes other than mental health symptoms should be considered in a representative sample as well, including changes (positive and negative) in relationships, school performance, and parenting. Overall, the results point to important interactions among various kinds of stressful events and a need to continue to study various forms of stressful events simultaneously.

Methods are needed for quantifying the potency and differential effects of risk factors to identify at-risk groups for theory building and intervention. Traditional methods for constructing war exposure measures are poorly suited to "unpack" differential relations between specific types of exposure and specific outcomes. This study of 881 Bosnian adolescents compared both *common factor–effect indicator* (using exploratory factor analysis) versus *composite causal–indicator* methods for "unpacking" dimensions of war exposure and their respective paths to postwar adjustment outcomes. The composite method better supported theory building and most intervention applications, showing how multitiered interventions can enhance treatment effectiveness and efficiency in war settings. Used together, the methods may unpack the elements and differential effects of "caravans" of risk and promotive factors that co-occur across development.

In the aftermath of wars and other catastrophic events, questions concerning whom and how to help—that is, *how to best identify at-risk groups and allocate scarce mental health resources*—confront every practitioner and agency that strives to promote the recovery of affected youths and families. Efforts to address these questions have contributed to our growing knowledge base by improving the method-

ological rigor of disaster research (Norris, Galea, Friedman, & Watson, 2006), building theory by identifying the correlates and sequelae of war exposure (e.g., Dyregrov, Gupta, Gjestad, & Mukanoheli, 2000; Macksoud & Aber, 1996), and field-testing interventions (e.g., Layne et al., 2008). These studies have identified a broad range of types of distress in war-exposed youths, including posttraumatic stress disorder (PTSD), depression and other internalizing disorders, externalizing behaviors, impaired school performance, and disturbances in personality formation and moral development (see Barenbaum, Ruchkin, & Schwab-Stone, 2004; Entholt & Yule, 2006; Fayyad, Karam, Karam, Tabet, & Ghosn, 2004; Shaw, 2003).

Although the literature identifies a general dose–response relation between the magnitude of war exposure and youth postwar distress, studies are providing growing evidence of *differential relations* between specific trauma-related risk factors and specific posttraumatic adjustment outcomes (Layne, Beck, et al., 2009). In their review, Fayyad et al. (2004) note that for at least half of war-exposed youths, PTSD reactions decrease on their own in the postwar aftermath, whereas other youths continue to meet full PTSD diagnostic criteria or experience delayed-onset stress reactions. The persistence of these reactions is linked to both the degree of severity of initial trauma exposure as well as the presence of postwar family stressors, such as maternal dysfunction and poverty. Such findings underscore the influential roles played not only by the specific *types* of trauma and loss to which youths are exposed but also of associated moderators and mediators of youth postwar adjustment (see Miller & Rasmussen, 2010). For example, evidence that having one's parent killed and the disappearances of loved ones are especially traumatogenic (Shaw, 2003) suggests that war-related causal risk factors may differ significantly in their potency. In addition, a gender-moderated effect is evident in findings that war-exposed girls generally manifest higher levels of anxiety and mood symptoms than boys, whereas boys manifest higher rates of externalizing behavior (Pat-Horenczyk et al., 2009; Shaw, 2003). The importance of mediators is underscored by evidence that different war-related causal risk factors may exert their effects on postwar outcomes through different pathways of influence. For example, Entholt and Yule (2006) report that PTSD symptoms in refugee youths are more strongly linked to earlier war trauma and subsequent resettlement strain, whereas depression symptoms are more strongly linked to recent stressful life events and current maternal mental health. Taken together, these studies constitute important early progress in understanding the mechanisms and processes that underlie the etiology and clinical course of youth psychosocial maladjustment following war-related trauma and loss.

However, the progress made in the war and disaster literature in identifying the pathways through which specific types of trauma exposure differentially influence posttraumatic psychosocial adjustment is impeded by four methodological practices. As discussed by Netland (2001, 2005) and Barenbaum et al. (2004), these practices include: (a) the inappropriate use of the *common latent factor with effect indicators model* (i.e., factor analysis) to derive the dimensionality of trauma exposure measures; (b) inadequate event sampling in scale construction (e.g., selecting a best *sample* of ''internally consistent'' events vs. a comprehensive event *census*), including the practice of importing existing trauma exposure measures into new settings that differ markedly from those for which the measures were created; (c) the use of total-scale summative scoring (e.g., creating a unit-weighted ''total war exposure'' score that intermixes many different types of trauma); and (d) the use of scale reliability indices (e.g., Cronbach's alpha; Cronbach, 1951) that are incompatible with the psychometric assumptions or particular applications of the measurement model being used.

Consequently, although the literature provides compelling evidence that war exposure is generally harmful to youth adjustment, its ability to explain *which* types of exposure are most harmful, for *which* outcomes, for *whom*, *how* they transmit their effects, and *how* this knowledge should guide intervention, is much more limited (Layne, Warren, Watson, & Shalev, 2007). Accordingly, although noting a general dose–response relation between trauma exposure and mental health, Barenbaum et al. (2004) offer the caveat that different types of trauma relate differentially to PTSD and other outcomes, such that some traumatic events have only moderate or negligible long-term effects whereas others are devastating. The authors note that the literature is largely unable to explain how or why this occurs. Such shortcomings recently led an APA task force to conclude that although some posttrauma *indicators of risk* have been identified, no method exists for accurately predicting whether specific youths will recover on their own or instead require some intervention. The task force called for the development of ''well-validated risk assessment tools that can be feasibly implemented *in diverse settings and for diverse traumatic events and that will help identify the high-risk youth and families who are in need of* *clinical services*" (APA Presidential Task Force, 2008, p. 6, italics added).

Developing risk assessment methods and tools for quantifying the potency and differential effects of specific types of trauma exposure that are valid and useful across diverse settings carries great promise for advancing the field, especially through building theory, enhancing risk screening and intervention, and guiding social policy (Kraemer et al., 1999). Specifically, a method that aggregates into the same test dimension *equifinal* causal risk factors (i.e., factors that lead to the same causal consequences; Richters, 1997) will help to quantify the differential effects of specific types of risk factors on specific outcomes. This practice can build theory by clarifying the etiological significance of specific types of trauma and loss for specific outcomes and the differential pathways of influence that interconnect them. In turn, clarifying *who is at risk for what outcome* will improve risk screening and triage by assigning groups with different types of trauma and loss (e.g., traumatic bereavement) to intervention modules that target those types of distress for which members are at greatest risk (e.g., maladaptive grief reactions). Equally valuable, knowledge of key pathways of influence can improve the effectiveness and efficiency of interventions by identifying "high-value" targets for intervention. This will guide treatments in addressing not only "endpoint" distress—related *outcomes* (e.g., PTSD, depression, traumatic grief), but also *key causal contributors to* those outcomes (e.g., trauma and loss reminders).

Given these advantages, we propose that it is a propitious time to reevaluate the ways in which war exposure is measured. Much can be gained by supplementing the traditional test construction method of factor analysis and related approaches (e.g., Dyregrov et al., 2000) that "unpack" trauma exposure into dimensions that *model the structure of event co-occurrences*, with a method that "unpacks" exposure into dimensions that *model the occurrences of specific types of trauma and loss and their differential links to psychosocial consequences*. As part of this reevaluation, candidate methods for constructing measures of trauma exposure should be evaluated according to their promise for strengthening research methodology, theory, and intervention. Specifically, a method promotes methodological rigor through proper model specification, improved model fit, increased variance explained, strengthened causal inference, and greater clarification of the "real-world" structure of relations between variables (Mulaik, 2009). A method furthers theory building by enhancing the description, explanation, and prediction of ways in which stress-related disorders originate, persist, abate, recur, lead to dysfunction, and are counteracted by promotive and protective factors within and across specific developmental periods. Last, a method enhances intervention by improving the accuracy of risk detection and triage, identifying appropriate treatment components and modalities (e.g., classroom vs. small group treatment; Layne et al., 2008), and prioritizing intervention foci, such as targeting family versus peer versus adult mentor social support in a postwar psychosocial program (Layne, Warren, et al., 2009).

Some Essential Details: The Common Factor–Effect Indicator and Composite–Causal Indicator Models

Developing a method for accurately predicting who is at risk for what outcomes will involve evaluating two fundamentally different approaches to conceptualizing, measuring, and modeling trauma exposure. These are the *common latent factor with effect indicators model* (i.e., reflective–indicator model; MacDonald, 1999), which emphasizes the *structure of co-occurrence among events*, and the *composite variable with causal indicators model* (i.e., formative-indicator model; Grace & Bollen, 2008), which emphasizes the *structure of event occurrences and their respective consequences* (e.g., personal income and education both contribute to socioeconomic status). MacKenzie, Podsakoff, and Burke (2005) propose that the two models can be differentiated in four ways: (a) Effect indicators *manifest or reflect* the underlying construct, whereas causal indicators *define* the composite. (b) Effect indicators (assuming equivalent reliability) are *interchangeable*, whereas each (nonredundant) causal indicator is a *unique constitutive element of* the composite. (c) *Covariation* among effect indicators is both expectable and desirable due to the influence of a shared common factor, whereas causal indicators are not necessarily expected to covary (indeed, high covariation may reflect excessive redundancy). And (d) effect indicators, but not causal indicators, are expected to *share a common set of causal precursors and causal consequences* because they emanate from a common causal origin. The models can also be rationally differentiated by considering whether a change in the *common factor* necessarily precedes a change in its "effect" indicators (e.g., a siege *causes* a city to be surrounded and shelled), or conversely, whether a change in the "causal" indicators necessarily precedes a change in the resulting *composite* (surrounding and shelling a city *causes or creates* a siege).

Figure 1. (A) A common latent factor–effect indicators model. (B) A composite–causal indicators model. (C) Differentiated "real-world" causal structure between four causal risk factors and two outcomes. (D) A composite–causal indicators model of the variables in (C). (E) A common latent factor–effect indicators model of the variables in (C). (F) Incorrect causal inference regarding the variables in (C) produced by statistical artifact: Dropping *friend killed* forces both life threat indicators to act as its proxies. (G) A hierarchical confirmatory common latent factor–effect indicators model. (H) A bifactor confirmatory common latent factor–effect indicators model.

The *common factor–effect indicator* model (Figure 1A) derives from classical test theory and undergirds many traditional test construction tools, including exploratory factor analysis (EFA), confirmatory factor analysis (CFA), and Cronbach's alpha (Cronbach, 1951; see also Bollen & Lennox, 1991). The common factor model, often paired with alpha, has been in use for over 20 years to derive "internally consistent" dimensions of trauma exposure (e.g., Dyregrov et al., 2000). A core assumption of the model is that the indicators are *homogeneous* (i.e., share a *common causal origin*; Borsboom, Mellenbergh, & van Heerden, 2003). Arrows leading from the latent common factor to each "effect" indicator place the locus of causation within the factor, signifying that it explains the variances of the indicators. The proportion of each indicator's variance explained by the common factor variance is denoted by its squared factor loading (λ^2). The model-implied covariance between any two indicators is reproduced by multiplying their factor loadings ($COV_{jk} = \lambda_j\lambda_k$; MacDonald, 1999), signifying that *indicators covary because, and to the extent that, they are jointly caused by causal processes underlying the common factor*. *U* denotes each item's uniqueness as comprised of both unsystematic (i.e., random) error variance and systematic variance not shared with the common factor (e.g., method variance). Although alpha assumes both item homogeneity (a strict assumption) and tau equivalence (equivalent factor loadings, a stricter assumption), it tests neither assumption but is instead a simple function of the number of test items and the average interitem bivariate correlation (Sijtsma, 2009).

In contrast, the *composite–causal indicator model* (Figure 1B; Grace & Bollen, 2008) does not assume indicator homogeneity. Rather, each of the indicators contributes to the composite (denoted by arrows leading from the indicators to the composite), placing the locus of causation in the indicators. Because each indicator is an independent contributor to the composite, covariation or "internal consistency" among indicators (Figure 1B, paths a–f) is of peripheral interest (Diamantopoulos, Riefler, & Roth, 2008). The error variance is specified at 0, signifying that composite values are a linear combination of the indicators. The composite thus mediates the predictive effects of its indicators on outcomes and constrains each indicator to have the same proportional influence on all outcomes (e.g., Indicator 1 exerts equivalent predictive effects on Outcomes A and B in Figure 1B; Franke, Preacher, & Rigdon, 2008). The model is flexible: Causal risk factors that are equifinal in relation to specified outcomes but known a priori to differ in their respective potencies can be aggregated into *fixed weight composites* (in which weights are fixed to different magnitudes to model differential effects); alternatively, risk factors of unknown potencies can be aggregated into *unknown weight composites*. Correctly specified composites function as "unitary entities" in relation to other variables (e.g., causal indicators theorized to be equifinal should relate in similar ways to their theorized causal consequences; Wilcox, Howell, & Breivik, 2008). Accordingly, equifinal causal risk factors (e.g., father's death by shelling, aunt's death by suicide, brother's death by car accident) may exert similar effects on a specified set of outcomes (PTSD, traumatic grief) *irrespective* of whether they share a common origin, co-occur, covary, or manifest "internal consistency." Thus, *when the aim is to model links between event occurrences and their respective consequences*, risk factors that *are* equifinal in reference to focal outcomes may be assigned to the same composite, whereas risk factors that co-occur, covary, and manifest internal consistency, but are *not* equifinal, may be assigned to different composites. Given its focus on modeling consequences, the composite approach is well suited for modeling not only relations between "real-world" objective events (e.g., paths from war-time losses to postwar hardships) but also between objective events and subjective experiences (e.g., paths between trauma and distress). The degree of discrimination used in combining events into dimensions depends on the desired degree of specificity in measuring their differential effects.

Contrasting the Two Approaches: Conceptualizing, Measuring, and Modeling Trauma Exposure

A comparison of the common factor versus composite models should be qualified by two caveats. First, neither is entirely theory driven nor entirely data driven: Although strongly empirical, the common factor approach requires rational judgment pertaining to such activities as selecting extraction and rotation algorithms, specifying factor-loading cutoff values, and factor interpretation. Further, the composite approach should be guided by both theory and empirical evidence concerning links between causal risk factors and their consequences. Thus, the approaches may be conceptualized as lying on opposing ends of a bipolar continuum ranging from greater emphasis on empirical evidence to greater emphasis on theory.

A second caveat is that the strengths and weaknesses of each model depend on the application. Consider the "real-world" differentiated model in Figure 1C, in which all risk factors are equifinal for PTSD symptoms, but only *father killed* and *close friend killed* are equifinal for traumatic grief. The utility of each approach rests on which portion of the model—the *structure of relations between co-occurring risk factors*, versus the *structure of the occurrence of specific causal risk factors and their differential consequences*—is of primary interest. Because the common factor model draws exclusively on the *covariances between risk factor indicators* (paths a–f), it is useful for aggregating clusters of traumatic events that co-occurred sufficiently to produce coherent factors. This focus on the structure *among* risk factors gives the common factor model three potential strengths. First, each indicator is a risk marker for the other indicators. Second, all indicators are *general* risk markers for all outcomes (APA Presidential Task Force, 2008). Third, the model can ''unpack'' complex events (e.g., wars) into often-meaningful clusters of co-occurring events (e.g., sieges). However, because it is designed to extract ''best internally consistent'' *samples* of covarying events, the model may drop events that *occur, but do not systematically co-occur*, that would be captured via event census (Netland, 2005). Indeed, the only conditions under which the common factor model is likely to produce ''clean'' equifinal test dimensions are when all equifinal events (e.g., all types of traumatic bereavement) happen to covary strongly, and all *non*equifinal events (bereavement vs. material loss) do not. Such conditions are unlikely to emerge in war-related settings, although there may be rare exceptions (cf. Macksoud & Aber, 1996).

Figure 1D presents a composite model of the relations in Figure 1C. Given its emphasis on causes and consequences, including differential relations (see paths g–l), this approach conducts a *census* of trauma exposure types for two reasons. First, each (nonredundant) causal indicator is a constitutive element of the composite and thus indispensable (Bollen & Lennox, 1991). Second, events that occur but do not *co-occur and covary* with other risk factors may nevertheless exert potent influences (see Figure 1C, paths j and l from *father killed*, which does not covary). The ''data input'' used by the composite model thus centers on *paths linking risk factors to their theorized consequences* (Figure 1C, paths g–l). The composite model is thus well suited not only to aggregate equifinal risk factors into common dimensions, but also to assign causally diverse events to different composites to facilitate the detection of differential relations.

Model–Application Mismatch: Using the Common Factor Model to Unpack Risk Factor–Consequence Links

Given its long-standing use (see Barenbaum et al., 2004; La Greca, Silverman, Vernberg, & Roberts, 2002), potential drawbacks that may arise when the common factor model is used *in applications focusing on the causal consequences of war exposure* should be considered. A model that ''packs'' types of war exposure into dimensions based on their covariance structure (Figure 1C, paths a–f) may indeed be ill suited to ''unpack'' the differential causal effects *of* specific types of exposure on specific consequences (paths g–l). In such applications, any of six conditions may create ''model–application mismatches'' that dilute, distort, and obscure ''real-world'' differential relations. These include: (a) The aim is to detect differential relations between specific types of causal risk factors and specific outcomes. (b) Events that co-occur are *not* equifinal (Figure 1C, paths g–j). (c) Events that do not co-occur *are* equifinal (paths g, h, and *k*). (d) Ambiguity in test scores (produced by combining different causal risk factors that exert different effects) is costly. (e) *Sampling*, rather than conducting a *census* of, trauma types will create costly false negatives (e.g., youths whose fathers are killed are not detected), costly false positives (youths needing only general support receive specialized services), or lead to incorrect conclusions about causal relations. And (f) researchers wish to create variables and assessment tools that have predictive utility at the individual case level and are transportable across diverse settings and diverse traumatic events (APA Presidential Task Force, 2008).

Figure 1E depicts a scenario that may arise when the common factor model is used to unpack the ''real-world'' consequences of war exposure (as found in Figure 1C) and contains three major misspecification errors. These include the *violation of the assumption of homogeneity*, the *loss of differential relations*, and the *exclusion of an influential causal risk factor*. The first error, *violation of indicator homogeneity*, arises because *Siege Exposure* is modeled as the *cause* of shooting and shelling, when instead *these acts define and initiate a siege and ceasing them will cause it to end* (MacKenzie et al., 2005). This fact repudiates the assumption of indicator homogeneity and the associated need to aggregate (or disaggregate) indicator-level risk factors into test dimensions on the basis of their covariance structure. Why should causal risk factors (including those that exert equifinal effects) necessarily co-occur or covary if they do not share a common causal origin? Indeed, modeling war exposure as a homogeneous latent common factor is incompatible with PTSD diagnostic criteria because the etiology of the disorder lies in observable *indicator-level* Criterion A1 events, such as mortar shell attacks, rather than unobservable ''latent'' causal processes. The indicators thus do not *share* a common origin with outcomes (e.g. ''latent'' sieges do not cause shelling on one hand *and* PTSD on the other); rather, *indicators are etiological risk factors for PTSD* (*shelling* can cause PTSD). Causally misspecified common factor models may thus lead to the logical fallacy of *affirming the consequent*: (a) If test items are homogeneous, then they load a common factor and show evidence of internal consistency. (b) This set of indicators loads a common factor and produces a high alpha value. (c) *Therefore, these indicators are homogeneous and share the same causal consequences* (MacKenzie et al., 2005). Thus, well-intentioned researchers may create a test of "siege exposure" and attempt to model, assess, or treat its "sequelae."

The second specification error found in Figure 1E is the *loss of differentiated relations* (see Figure 1C, paths k and l). Sieges and other campaigns often generate clusters of co-occurring events (Figure 1C, paths b, d, and e) that a common factor approach will aggregate. However, covariation between types of war exposure does not reflect indicator homogeneity, but rather, *perceived event co-occurrences*. "Packing" types of war exposure into dimensions on the basis of their covariance structure is thus likely to intermix causally diverse (i.e., nonequifinal) risk factors into the same dimension. Such causally diverse dimensions are especially likely to emerge in inherently complex war and disaster settings where many different types of trauma and loss co-occur. Causally diverse test dimensions are of concern for two reasons. First, creating summative ("unit-weighted") aggregate variables to model or assess the "sequelae" of a given dimension of war exposure implies that *all indicators are equifinal and equally potent* causal risk factors for all its modeled sequelae. For example, summative scoring of the model in Figure 1E implies that both life-threat events and *friend killed* are *equivalent and interchangeable* causal risk factors for both PTSD and traumatic grief (MacKenzie et al., 2005). Second, pooling the variances of causally diverse risk factors into the common factor variance (thereby increasing *intradimension* causal diversity) decreases their sensitivity to detecting the differential effects of different types of risk factors. Indeed, major discrepancies may arise between the *causal effects* of risk factors in the "real world" and the *magnitudes of their factor loadings*. In Figure 1C, the effects of the life-threat items on traumatic grief are negligible, whereas *friend killed* and *father killed* may exert moderate and potent effects, respectively. However, the covariances among indicators (paths a–f) may produce large loadings for both life-threat items and moderate and negligible loadings for *friend killed* and *father killed*, respectively. The common factor variance may thus consist mostly of variance extracted from causally weak indicators. This may both reduce the strength of paths from the common factor to outcomes (Figure 1E, path b) and lead to erroneous conclusions regarding the potencies of the respective indicators or of that dimension.

The third misspecification error in Figure 1E is the *loss of a potent causal risk factor* (*father killed*) due to its lack of covariation with other risk factors (Figure 1C, paths a, c, and f). Because it extracts variables based on their covariance structure, the common factor model is susceptible to dropping two types of events. These include *events that occur but do not systematically co-occur* with other modeled risk factors (e.g., random or unrelated events), and *events whose measurement is compromised by statistical artifact* (e.g., restricted variance due to floor effects). The exclusion of causal risk factors may reduce proportions of explained variance (reducing predictive precision) and bias model parameters in ways that overestimate the vulnerability of exposed subgroups (due to "unexplained" elevations in distress scores; Netland, 2005). Omitting causal risk factors also compromises test validity by reducing the correspondence between a test and the "real-world" structure among variables it purports to measure (Borsboom, Mellenbergh, & van Heerden, 2004) and can decrease the sensitivity of screening instruments in ways that lead to false negatives and poor matches of individuals to treatments (Kraemer et al., 1999; Netland, 2001). Omitted causal risk factors can also create spurious statistical artifacts. Figure 1F depicts how distortions of the "real-world" scenario in Figure 1C can lead to faulty conclusions about causal relations. Statistically independent *father killed* does not covary, whereas high endorsement rates for *friend killed* produce a ceiling effect that artificially restricts its covariance with both life-threat items *even though these three types of events co-occur in that setting*. The exclusion of *friend killed* forces both life-threat items to act as its proxies. The resulting biased model parameters may undermine theory building by *under*estimating the etiological significance of traumatic death in relation to traumatic grief, while *over*estimating that of life threat (Netland, 2005). The model may also impede intervention by increasing false negatives ("high-risk" bereaved youths are not detected) and false positives (youths exposed to low-potency risk factors receive specialized treatment components).

Appropriate Use of the Common Factor–Effect Indicator Model to Clarify Differential Relations

Notwithstanding these caveats, we emphasize the utility of the common factor model for clarifying differential relations among multidimensional constructs whose causal structure is compatible with indicator homogeneity (e.g., Krueger, 1999). These include both the *hierarchical* and the *bifactor* confirmatory factor analytic models (Figures 1G and 1H; Chen, West, & Sousa, 2006). Both models allow a priori model specification of hypothesized dimensions and carry a lower risk of bias in model parameters than EFA (Little, Lindenberger, & Nesselroade, 1999). The latent structure in both models consists of a general factor and one or more specific components for different subsets of items. Although "specific" components are often used to model potentially confounding methodological effects, they can also model multidimensional structures among "real-world" variables. In contrast to traditional common factor models that contain multiple *separate* factors, the hierarchical and bifactor models each allows an item to reflect both general characteristics shared with all of the other indicators and characteristics unique to specific item subsets. The design of the bifactor model ensures that the latent-specific components are uncorrelated with one another and with the general factor. These features make the models useful for studying the breadth and specificity of complex constructs, including *convergent validity* (via the general factor) and *discriminant validity* (via the specific components) in multifaceted conceptual domains. The models permit testing of measurement and structural hypotheses relating to differential relations while addressing potential collinearity among latent components and controlling for broader shared variance. Although the hierarchical and bifactor models are difficult to distinguish on purely empirical grounds, each embodies a distinctive theoretical structure that may be plausible within a given setting. Moreover, the common factor approach can also, like the composite–causal indicator approach, prioritize the clarification of structural relations between constructs over internal consistency. Little et al. (1999) demonstrate that the validity of common factor models often increases when indicators are selected (even those of "poor" psychometric quality) that clearly demarcate construct domains and boundaries between constructs. Conversely, selecting only highly correlated indicators in the interests of maximizing internal consistency may lead to test bias and distorted estimates of the construct's relations with other constructs.

A Comparison of the Common Factor and Composite-Based Approaches in Postwar Bosnian Youth

Study rationale. Given the potential benefits of each approach, as well as potential problems arising from model–application mismatches, this study compared the performance of a common factor–effect indicator model (using EFA) versus a composite–causal indicator model. The study focused on the potential of each model to (a) build theory capable of explaining differential risk factor–outcome relations, (b) predict which groups are at risk for specific types of distress, and (c) increase the effectiveness and efficiency of interventions. Because low endorsement rates restricted the variances of many war exposure items (e.g., personal injury), the composite approach relied only on theory and prior knowledge to assign specific types of trauma to exposure dimensions. Further, because the cross-sectional design precluded causal inference, we investigated only the *predictive effects* of risk factors (including theorized mediators) on outcomes. Last, given space limitations and our focus on "unpacking" the covariance structure and consequences of risk factors, no gender effects were tested.

Study setting. The 1991–1995 civil war in the Former Yugoslavia exemplifies the brutal nature of modern armed conflict and its stressful aftermath. The 1992–1995 Bosnian conflict led to the traumatic deaths of close to 100,000 people, approximately 41% of whom were civilians, and the displacement of 1,800,000 people, many of whom faced years of subsequent hardship as internally displaced persons or war refugees (Ahmetasevic, 2007). The war led to widespread traumatic deaths, physical injury, traumatic disappearances, major disruptions in social institutions, and brutal mistreatment through acts of assault, torture, rape, and starvation inflicted on detained civilians and prisoners of war. Many military strategies directly targeted civilians, including sieges of cities and protected enclaves, ethnic cleansing campaigns, and genocidal operations. These campaigns generated widespread exposure to direct life threat, the witnessing of traumatic deaths and serious injury, deprivations in basic necessities, exposure to the elements, and the forced exodus of entire regions in refugee flights (Powell & Duraković-Belko, 2002).

Study design and hypotheses. Data were collected in the fall of 2000 (nearly 5 years postwar) in a screening survey used in a postwar psychosocial program for war-exposed adolescents (Layne et al., 2008). The survey was administered in nine heavily war-exposed secondary schools in Central Bosnia and was based on a developmental model of childhood traumatic stress (Pynoos, Steinberg, & Wraith, 1995). Survey items measured a broad range of traumatic experiences, theorized mediators of youth postwar adjustment including trauma reminders and adversities (Layne et al., 2006), and distress-related outcomes. Because the common factor approach models the *structure of event co-occurrences*, we predicted that EFA-derived factors would reflect major military strategies employed in the Bosnian conflict (e.g., sieges, ethnic cleansing; Hypothesis 1) and would substantively differ in their composition compared with the rationally derived composite dimensions (Hypothesis 2). We also theorized that highly "traumatogenic" war-time risk factors (e.g., life threat, traumatic death) would exert direct predictive effects, whereas the predictive effects of less-traumatogenic war-time risk factors would be fully mediated by postwar trauma reminders and adversities. We thus predicted that the *partially mediated* version of each model would fit better than its *fully mediated* (indirect effects only) counterpart (Hypothesis 3). Last, we predicted that the composite–causal indicator model would show more differentiated relations between theorized causal risk factors (including *prewar trauma* and different types of *war-time trauma*), theorized mediators (including *postwar adversities* and *trauma reminders*), and outcomes (including *posttraumatic stress, depressive, and traumatic grief reactions*; and *functional impairment*) than the common factor model (Hypothesis 4).

Method

Measures

All measures were reviewed for cultural appropriateness and forward- and back-translated by doctoral students in psychology at the University of Sarajevo. Measures were then combined into a self-report screening survey and administered to classrooms by trained school counselors. All distress measures except the OQ Somatization Subscale used a standard 5-point Likert-type scale measuring the frequency with which each symptom was experienced during the last month ranging from 0 (*none of the time*) to 4 (*most of the time*). All trauma and stressful life event exposure measures used a dichotomous scale ranging from 0 (*event did not occur within the specified time frame*) to 1 (*event occurred at least once within the time frame*). Prior to modeling, we transformed the observed score on each scale or subscale by dividing by the total number of items to form an *item-level average score* ($\bar{x}_i$). Calculating the item-level average enhanced interpretation by benchmarking the summative scale score against the original item-level metric (averages of Likert scale scores ranged from 0 to 4; averages of exposure scale scores ranged from 0 to 1) while controlling for between-scale differences in scale length and scale variance.

Participants

Participants consisted of ($N = 881$) students attending nine Central Bosnian secondary schools during the 2000–2001 school year who were screened for their appropriateness for a UNICEF-sponsored trauma and grief-focused psychosocial program (Layne et al., 2008). The sample consisted of 55% ($n = 480$) girls and 44% ($n = 390$) boys (1% not reported), ranging from 13 to 19 years old ($\overline{X} = 15.79$, $SD = 1.10$) and from the 1st to the 3rd year in school ($\overline{X} = 1.87$, $SD = 0.82$). We randomly assigned approximately half of the participants to one of two subsamples. We used Subsample 1 for model construction, and Subsample 2 to replicate (without further modification) the model parameters constructed using Subsample 1. The two subsamples did not significantly differ ($p < .05$) in age, sex, grade in school, or school affiliation.

Measures

Prewar Trauma Exposure Index (Layne, 1999a) is a 10-item self-report measure of exposure to a range of prewar traumatic experiences. Items were generated from field research and from adapting items from the Stressful Life Events Screening Questionnaire (SLESQ; Goodman, Corcoran, Turner, Yuan, & Green, 1998). Items are measured on a yes–no scale ("Before the war, did you ever have a life-threatening illness?"). Items 1–9 (the 10th is open-ended) were summed into a composite score (total sample $\overline{x_i} = 0.08$).

War Trauma Screening Inventory (WTSI; Layne, Stuvland, Saltzman, Djapo, & Pynoos, 1999) is a 49-item self-report measure of exposure to different types of war-related trauma and loss. Items were drawn from Bosnian field research and from a literature review (e.g., Macksoud & Aber, 1996). Items were analyzed in two ways: For the composite–causal indicator approach, the first author drew on proposed "common denominator" dimensions of trauma exposure (e.g., La Greca et al., 2002; Pynoos

Table 1
Composite–Causal Indicator-Derived Dimensions of War Trauma Exposure

Direct Exposure	Witnessing Violence	Life Threat	Traumatic Death[a]	Harm to Loved Ones	Threat to Loved Ones	Loss and Displacement	Separation from Loved Ones
In serious accident Life-threatening cold Deprived of food/water Exposed to disaster Physically tortured Taken prisoner Unwanted sexual contact Was physically injured Victim of serious crime Became seriously ill Was physically assaulted	Saw dead body Saw severely injured person Saw serious accident Saw property destruction Saw someone being killed or injured Touched/carried wounded or killed person Saw distraught person Witnessed assault Witnessed person taken prisoner or abducted Witnessed torture Witnessed loved one being harmed or killed	Grenade/bomb exploded nearby Bullet came close Strongly believed would be hurt or killed Verbally threatened with harm/death Enemy soldiers entered home	Close friend killed Mother killed Sibling killed Extended family member killed Loved one committed suicide Loved one killed in violence not due to war Father killed	Loved one tortured Loved one assaulted Loved one taken prisoner or detained Loved one seriously injured Loved one had life-threatening illness	Loved one had very dangerous duties Loved one threatened with harm/death Loved one went missing	Left country due to war Forced from home Left village/town because of war Changed to new school because of war Lived in refugee center Home badly damaged Lost beloved pet	Separated from loved one when greatly feared for their safety Separated from both caregivers for month or longer

[a] The item *loved one died of natural causes* was dropped from the composite–causal indicator-derived dimensions due to its ambiguity as a traumatic stressor.

et al., 1995) to divide items into eight content domains consisting of *Direct Exposure* (11 items; total sample $\overline{x_i} = 0.066$), *Witnessing Violence* (11 items, $\overline{x_i} = 0.307$), *Life Threat* (5 items, $\overline{x_i} = 0.354$), *Traumatic Death* (7 items, $\overline{x_i} = 0.055$), *Harm to Loved Ones* (5 items, $\overline{x_i} = 0.199$), *Threat to Loved Ones* (3 items, $\overline{x_i} = 0.309$), *Loss and Displacement* (7 items, $\overline{x_i} = 0.341$), and *Separation From Loved Ones* (2 items, $\overline{x_i} = 0.362$). Table 1 presents a breakdown of WTSI items by the eight domains. For the common factor–effect indicator method, five war exposure subscales were derived using EFA (see Table 2) consisting of *Siege Exposure* (18 items including 1 reverse-scored item, total sample $\overline{x_i} = 0.369$), *Expulsion and Displacement* (9 items including 2 reverse-scored items, $\overline{x_i} = 0.459$), *Detention and Maltreatment* (9 items, $\overline{x_i} = 0.095$), *Harm to or Death of Loved One* (7 items, $\overline{x_i} = 0.228$), and *Personal Assault or Injury* (2 items, $\overline{x_i} = 0.03$).

Postwar Trauma Exposure Inventory (PWTEI; Layne, 1999b) is a 13-item self-report measure of exposure to nonwar-related traumatic events. Items were adapted from the SLESQ and from field research in postwar Bosnia. Items include general traumatic events ("Since the war, has a loved one attempted suicide?") as well as events characteristic of the Bosnian conflict ("Since the war, has a loved one who disappeared during the war been declared dead?"). The PWTEI contains four content domains that were rationally derived by the first author, including *Direct Exposure* (6 items, total sample $\overline{x_i} = 0.062$), *Witnessing* (2 items, $\overline{x_i} = 0.123$), *Harm to Loved Ones* (3 items, $\overline{x_i} = 0.101$), and *Traumatic Death* (2 items, $\overline{x_i} = 0.072$).

Trauma Reminders Screening Inventory (TRSI; Layne, Steinberg, & Pynoos, 1998) is a 17-item self-report measure of the frequency of respondents' exposure to reminders of war-related traumatic events during the past month and associated functional impairment. Using theory and EFA, items were partitioned into *general trauma reminders* (8 items; e.g., news of war atrocities, political instability), *interpersonal trauma reminders* (4 items; e.g., friends, family), and *trauma reminder-related interference* (3 items; e.g., impaired social relationships). Because the TRSI measures *perceptions* of being reminded (suggesting a common underlying causal process), alphas were calculated for each subscale (full-sample general α = .90, interpersonal α = .83, interference α = .85). We modeled general and interpersonal reminders as postwar mediating variables, and reminder-related interference as an outcome.

UCLA Reaction Index–Revised (RI–R; Steinberg, Brymer, Decker, & Pynoos, 2004) as used in this study is a 17-item self-report scale of symptom frequency during the previous month. Items correspond to the 17 *DSM–IV* PTSD criteria. The total scale has shown good internal consistency (α = .87), criterion-referenced validity in relation to a range of distress measures (.30 to .70), and 2-week test–retest reliability (.75) in postwar Bosnian youth (Layne, Warren, et al., 2009). Full sample, full-scale α = .87.

Depression Self-Rating Scale (Birelson, 1981) is an 18-item self-report measure of depressive symptoms. The original 3-point scale (for children) was modified to a 5-point frequency scale to increase developmental appropriateness and sensitivity to clinical change. The adapted version has shown acceptable internal consistency (α = .85), criterion-referenced validity (.37 to .62), and test–retest reliability (.64) in postwar Bosnian youth (Layne, Warren, et al., 2009). Full sample, full-scale α = .89 in this study.

Youth Outcome Questionnaire: Somatic Symptoms Subscale (Wells, Burlingame, Lambert, Hoag, & Hope, 1996) is an 8-item self-report measure of somatic distress (e.g., "I have headaches or feel dizzy") in children and adolescents. Items are measured on a 5-point frequency scale ranging from 0 (*never or almost never*) to 4 (*almost always or always*). Full sample, full-scale alpha α = .80 in this study.

Postwar Adversities Index (Layne & Djapo, 1999) is a 25-item self-report inventory of stressful life events and circumstances during the past 6 months. Items were rationally divided into two content domains by two independent raters who showed substantial interrater agreement using a dichotomous scale (κ = .79). Domains were *postwar existential adversities* (16 items; short on pocket money) and *interpersonal adversities* (6 items; living with people who fight). Items were coded according to valence (positive/neutral/negative life event) and independence/dependence by six independent raters on a 5-point scale. Raters showed excellent interrater reliability (α = .92) on valence and acceptable reliability (α = .79) on event independence. Chronic and acute events (Masten, Neemann, & Andenas, 1994) were both included. Because this study focused on adverse outcomes, only *negative-independent* life events were included; three events rated as *dependent* (pregnancy, getting into fights, and drug use) were dropped from analysis.

Procedure

To minimize potential stigmatization of individual students, school counselors selected entire classrooms with the highest prevalence rates of

Table 2

Percent Item Endorsement (%), Factor Loadings (F_i), Communalities (h^2), and Factor Correlations for Maximum Likelihood Factors Extraction and Promax Rotation on War Exposure Inventory Items

Item (type of trauma exposure during war)	%	F_1[a]	F_2	F_3	F_4	F_5	h^2

[a] Factor labels: F_1 = siege exposure; F_2 = expulsion and displacement; F_3 = detention and maltreatment; F_4 = harm to or death of loved one; F_5 = direct personal assault or injury. Primary factor loadings for each variable are bolded (decision rule: complexly loaded items with both loadings ≥ 0.50 load on both factors). [b] Heywood case (model estimates a negative residual variance) linked to low item variance (Comrey, 1992).

severely war-exposed students. Details regarding classroom selection, consent, and survey administration procedures are provided elsewhere (Layne et al., 2008). Measures and procedures were approved by an ad hoc institutional review board (IRB) formed of Bosnian mental health professionals and a UNCEF officer, and by the IRB of Brigham Young University.

Results

In a first step, we used Mplus 5.1 (Muthén & Muthén, 2009) to perform EFA on the full-sample covariance matrix formed by the 49 WTSI items. Maximum likelihood factors extraction was used in combination with promax (oblique) rotation. This procedure adjusts for missing values on observed variables and is suitable for binary-ordered categorical indicators (Muthén, 2002). After several preliminary extractions to estimate the number of factors and verify the absence of multicollinearity and the factorability of the correlation matrix, five factors were extracted. Table 2 presents item endorsement rates (in %), the rotated factor pattern matrix, communality (h^2) values, and a suggested label for interpreting each factor. Given the dichotomous scaling of the WTSI and low (< 10%) endorsement rates for many items, a liberal criterion ($\lambda_j \geq .40 = 16\%$ explained variance) was used to denote the primary factor loadings. The factors varied in quality as indicated by the number of variables with primary loadings and the sizes of the loadings. Factors were labeled *Siege Exposure* (Factor 1), *Expulsion & Displacement* (Factor 2), *Detention & Maltreatment* (Factor 3), *Harm to or Death of Loved One* (Factor 4), and *Direct Personal Assault or Injury* (Factor 5). Although interpretable, the solution poorly accounted for many items as denoted by low communalities and the loss of eight items (15% of total) due to low loadings. Among dropped items were events with low (*mother killed* = 1%), moderate (*father killed* = 10%), and comparatively high endorsement rates (*physically separated from loved one* = 60%) that correlated weakly with the retained items (full correlation matrix available from first author). Consistent with Hypothesis 1, the five EFA-derived factors reflected idiosyncratic features of the Bosnian war, including sieges, ethnic cleansing, and detention and maltreatment (Powell & Duraković-Belko, 2002).

In a second step, we evaluated the degree of convergence between the trauma exposure dimensions derived using the common factor versus the composite approach. The approaches were compared at two levels: (a) visually inspecting the item contents of the factors and composites (i.e., comparing Table 1 with Table 2), and (b) examining correlations between the respective subscale scores (a comparison matrix of factor/composite item overlaps and intercorrelations is available from the first author). In support of Hypothesis 2, the two approaches showed poor to moderate convergence at both levels of analysis and were consistent with our concerns regarding the *within-dimension* diversity of war exposure dimensions derived via the common factor model. Visual inspection revealed that *Siege Exposure* (Factor 1), *Detention & Maltreatment* (Factor 3), and *Harm to or Death of Loved One* (Factor 4) each contained a broad range of trauma types, such that their constituent items were broadly dispersed across the composite dimensions. For example, the item contents of Factor 1 (*Siege Exposure*) were distributed across the *Direct Exposure, Witnessing Violence, Life Threat, Traumatic Death, Threat to Loved Ones,* and *Loss and Displacement* composites. Further, the contents of Factor 3 (*Detention & Maltreatment*) were distributed across *Direct Exposure, Witnessing Violence, Life Threat,* and *Harm to Loved Ones*. The greatest degree of convergence was found in the overlap between *Expulsion*

& Displacement (Factor 2) and *Loss and Displacement* (Composite 7). The inverse loadings of *mother killed* and *sibling killed* on *Expulsion & Displacement* were unexpected. A second point of convergence was found in the overlap between the two items loading *Direct Personal Assault or Injury* (Factor 5) and *Direct Exposure* (Composite 1). However, because *Direct Exposure* contained six items not found in Factor 5, Factor 5 was a small subset of Composite 1.

The general lack of convergence between the two approaches observed in our visual inspection was reflected in a similar lack of differentiation in their subscale intercorrelations. The strongest points of convergence were found between *Siege Exposure* (Factor 1) and *Witnessing Violence* (Composite 2) ($r = .89$), and between *Expulsion & Displacement* (Factor 2) and *Loss and Displacement* (Composite 7) ($r = .97$). More generally, however, the factor–composite correlation matrix showed little clear evidence of between-method convergence between specific factors and composites, with the great majority of correlations falling in the low to moderate range ($.10 < r < .60$). For example, the Factor 3 (*Detention & Maltreatment*) subscale score correlated between $r = .40$ and $.60$ ($p < .01$) with those of the *Direct Exposure*, *Witnessing Violence*, *Life Threat*, and *Harm to Loved Ones* composites. In general, most factor subscale scores correlated indiscriminately with most composite subscale scores—an unsurprising finding given the high degree of dispersion of factor item contents across composites, and vice versa.

In a third step, we used Amos 16.0 (SPSS, 2009) to evaluate the fit of both the common factor and composite models in Subsample 1, and to evaluate the fit of the (unmodified) models in Subsample 2. We formed our models using observed variable path analysis—a variant of SEM conducive to modeling composite variables (Byrne, 2001). Given the exploratory nature of the study and the lack of guiding theory regarding relations between *specific* types of trauma and loss exposure, mediators, and outcomes, we used a conservative ''repeated pruning'' model-building strategy for both the composite and common factor method subsamples: We first created a semisaturated model that contained all possible paths linking (a) prewar trauma to each theorized mediator and each outcome, (b) each war-time exposure dimension to each theorized mediator and each outcome, and (c) each theorized mediator to each outcome. We then tested the model and deleted all nonsignificant paths with $p > .10$. We then retested the model and deleted all remaining nonsignificant paths with $p > .10$. In a final pass, we retested the model and deleted all nonsignificant paths with $p > .05$.

The composite–causal indicator model for Subsample 1 (see Figure 2) had good fit, $\chi^2(79) = 75.73$, $p = .58$; normed fix index (NFI) = .98, comparative fit index (CFI) = 1.0, root mean square error of

approximation (RMSEA) = 0 (90% confidence interval [CI] = 0–0.02), Hoelter (.01) = 676; and explained 55%, 46%, 27%, and 28% of the variance in PTSD symptoms, reminder-related functional impairment, depression, and somatic symptoms, respectively. Contrary to expectation, *Harm to Loved Ones* and *Threat to Loved Ones* did not exert significant predictive effects. Consistent with Hypothesis 3, the partially mediated model fit significantly better than its fully mediated counterpart, $\chi^2(8) = 55.04$, $p < .01$, indicating that prewar and some "traumatogenic" war-time exposures exerted direct predictive effects. Direct paths linked *prewar trauma* to PTSD symptoms, somatic symptoms, and functional impairment; war-time *traumatic bereavement* to PTSD symptoms and impairment; and war-time *witnessing violence* to impairment. Postwar *direct exposure* had a direct path to impairment, and postwar *witnessing violence* had direct paths to both impairment and depression.

The common factor–effect indicator model for Subsample 1 (see Figure 3), also had good fit $\chi^2(60) = 57.71$, $p = .56$; NFI = .98, CFI = 1.0, RMSEA = 0 (90% CI = 0–0.03), Hoelter (.01) = 705; and explained 55%, 46%, 28%, and 29% of the variances in PTSD symptoms, reminder-related functional impairment, depression symptoms, and somatic symptoms, respectively. Contrary to expectation, neither *Detention & Maltreatment* nor *Personal Assault or Injury* (derived from Factors 3 and 5, respectively) exerted significant predictive effects. Consistent with Hypothesis 3, the partially mediated model fit significantly better than the fully mediated model, $\chi^2(6) = 43.79$, $p < .01$. As in the composite model, *prewar* trauma had three direct paths to PTSD symptoms, somatic symptoms, and functional impairment. Notably, only *Harm to or Death of Loved One* (Factor 4) exerted a direct predictive effect (to depression) whereas the predictive effects of all other war-time variables were fully mediated. *Postwar Direct Exposure* had a direct path to reminder-related functional impairment, and *Postwar Harm to Loved Ones* had a direct path to PTSD symptoms.

In a fourth step, given the susceptibility of "repeated pruning" to sample-idiosyncratic over-fitting (Byrne, 2001), the goodness of fit of both models derived using Subsample 1 was tested (without further modification) in Subsample 2. The composite model had generally good fit, $\chi^2(79) = 159.58$, $p < .01$; NFI = .95, CFI = .97, RMSEA = .05 (90% CI = 0.04–0.06), Hoelter (.01) = 292. The composite model retained (at a significance level of $p < .05$) 28 (68%) of the 41 significant paths identified in Subsample 1 and explained 50%, 53%, 33%, and 30% of the variances in PTSD symptoms, reminder-related functional impairment, depression symptoms, and somatic symptoms, respectively. The common factor model also had generally good fit, $\chi^2(60) = 115.93$, $p < .01$; NFI = .96, CFI = .98, RMSEA

= .05 (90% CI = 0.03–0.06), Hoelter (.01) = 320. The common factor model retained 26 (72%) of the 36 paths in Subsample 1 and explained 51%, 53%, 33%, and 31% of the variances in PTSD symptoms, functional impairment, depression symptoms, and somatic symptoms, respectively. Reduced power (due to halving the sample), as well as restricted predictor variance, likely played roles in reducing the number of significant paths in both Subsample 2 models: In the composite model, 6 of 13 nonsignificant paths had predictor means < 0.10, and 10 of 13 had means < 0.15. In the common factor model, 4 of 10 nonsignificant paths had predictor means < 0.10, and 5 of 10 had means < 0.15.

In a fifth step, we tested Hypothesis 4 (beginning with Subsample 1) using effects decomposition (Byrne, 2001) to rank prewar, war-time, and postwar trauma risk factors by their total predictive effects on each outcome. Total effects for each risk factor were calculated by summing its direct effects (via direct paths) and indirect effects (via mediated paths). The top and bottom halves of Table 3 contain the risk factor rankings for the composite- and common factor-based approaches, respectively. Consistent with Hypothesis 4, the rankings for the composite model showed more differentiation than the common factor model between war-time trauma exposure and outcomes. Four war-time variables (*Life Threat*, *Traumatic Death*, *Witnessing Violence*, and *Loss and Displacement*) appeared in the top six rankings across outcomes in the composite model. In contrast, three war-time variables (*Siege Exposure*, *Expulsion & Displacement*, and *Harm to or Death of Loved Ones*) appeared in the top six rankings for the common factor model; *Siege Exposure* was the dominant risk factor for all outcomes. In a Subsample 2 replication analysis, the risk factor rankings in both models remained relatively stable (rankings not shown). Five war-time variables (the four from Subsample 1 plus *Separation From Loved Ones*) appeared in the top six rankings of the composite model. The common factor model contained the three war-time risk factors found in Subsample 1; *Siege Exposure* was again the dominant risk factor. *Prewar Trauma* was a predictor for all outcomes in both the composite and common factor models, in both Subsamples 1 and 2.

Discussion

This study addressed the question of how to conceptualize and model the multidimensional features of war exposure in ways that best facilitate theory building, strengthen methodological rigor, and improve risk screening and intervention. We presented two different approaches to modeling trauma exposure, the traditionally used *common factor with effect indicators model* and the *composite–causal indicators model*, and discussed their respective strengths in promoting these three aims. We focused on the core assumption of indicator homogeneity (i.e., are trauma exposure indicators *causal effects* of a common factor, or instead *contributors* to a composite?) and its far-reaching implications for how war exposure is conceptualized, measured, studied, and treated. The central question is: *Should specific types of trauma and loss be aggregated into dimensions according to their covariance structure, or instead, according to their consequences?* Given its widespread use via EFA and CFA, we reviewed limitations of the common factor model for applications that aim to model differential links between the occurrence of specific types of traumatic events and specific causal consequences. We posed a caveat: Applications that violate the assumption of indicator homogeneity (shelling cities *causes* sieges, not the reverse) can create "model–application" mismatches. Such mismatches can impede a call to move beyond identifying general "markers of risk" that only denote *who* may need *some form* of mental health services, to instead creating tools that can accurately predict *who* may need *which* types of mental health treatment components across different war and disaster settings (APA Presidential Task Force, 2008).

We further proposed that a *composite*-based approach that "packs" indicators into equifinal war exposure dimensions may better elucidate the differential effects of specific types of trauma on specific outcomes. A composite approach conceptualizes covariance between types of trauma exposure as reflecting *perceptions of event co-occurrence within specific settings*. Shedding unnecessary constraints linked to homogeneity (e.g., retaining only items that load a common factor and that increase "internal consistency") encourages an increased focus on equifinality through aggregating *specific types* of causal risk factors (e.g., traumatic bereavement) according to their common causal effects (PTSD, traumatic grief), and on identifying key *mediators* of those effects (trauma reminders, poverty, family strife).

We compared the common factor–effect indicator model (derived through EFA) to a rationally derived composite–causal indicator model in a split-sample replication design. Results generally supported the four study hypotheses and illus-

Note. R^2 = proportion of variance explained by model.
[a] Predictive effects were calculated using standardized models in which all outcomes and mediators were treated as continuous variables. [b] Six highest-ranking trauma exposure risk factors (by total predictive effect) for each outcome. [c] Direct + indirect effects versus total effects do not always correspond due to rounding error. [d] R^2 values for mediators in composite–causal indicator model = 24% for *General Trauma Reminders*, 12% for *Interpersonal Trauma Reminders*, 27% for *Existential Adversities*, and 19% for *Interpersonal Adversities*. [e] All four of the modeled putative postwar mediators are presented, ranked by direct predictive effect on the outcome, for both models. [f] Negative association suggests a suppressor effect. [g] % R^2 values for mediators in common factor–effect indicator = 19% for *General Trauma Reminders*, 7% for *Interpersonal Trauma Reminders*, 28% for *Existential Adversities*, and 20% for *Interpersonal Adversities*.

trated the relative strengths (and some potential drawbacks) of the two methods. The common factor model extracted clusters of co-occurring events that reflected idiosyncratic features of how the Bosnian conflict was waged (e.g., sieges, ethnic cleansing). The choice of test construction method is thus consequential, as the two methods derived dimensions of war exposure that differed substantially in their elements and relations with theorized mediators and outcomes. Both methods produced good model fit and explained substantial proportions of variance in outcomes. The partially mediated models fit better than their fully mediated counterparts, providing support for the hypothesis that "highly traumatogenic" prewar and war-time risk factors would exert direct predictive effects. However, most predictive effects were transmitted via postwar mediators (trauma reminders and adversities). The composite–causal indicator model produced clearer evidence of differential relations linking prewar and war-time trauma to postwar outcomes. In contrast, the common factor–effect indicator model showed less differentiation, as illustrated by the marked diversity in types of war exposure loading the Siege factor and its dominance as the primary risk factor for all outcomes.

We now discuss the implications of these findings by addressing five questions relating to theory building, strengthening methodological rigor, and improving risk screening, triage, and intervention.

Study Implications: Five Questions Regarding Theory Building, Research Methods, and Intervention

Question 1: Which measurement approach is preferable for modeling war exposure? The good fit of the Subsample 2 composite model is consistent with the assertion that specific types of trauma and loss (e.g., traumatic deaths) may generate similar consequences (e.g., PTSD) without necessarily sharing the same causal origin (i.e., processes underlying a common factor that *cause* the indicators to occur and co-occur) or manifesting "evidence" of indicator homogeneity. Our results suggest that which method is preferable depends on which part of the model—the *structure of co-occurrences among traumatic events*, versus the *structure of paths that differentially link the occurrences of specific types of trauma and loss to specific causal consequences*—is of primary interest. The "big picture" focus of the common factor model makes it well suited for "first-pass" questions that arise in the *situation analysis* phase of crisis response: "How was the war waged—which clusters of events co-occurred?" and "Who is at (global) risk due to the accumulation of co-occurring risk factors?" In contrast, the composite–causal indicator model is more useful for addressing deeper questions concerning *which types of trauma and loss place which subgroups at risk for which outcomes via which pathways of influence*. Such issues are more relevant to the needs assessment, risk screening/triage, case conceptualization, intervention planning, program evaluation, and prevention phases of response (Layne, Beck, et al., 2009) given that they address questions such as: "How should we prioritize trauma types according to severity?" "How can we use limited mental health resources most wisely?" and "Which mediating pathways should our interventions target and seek to interrupt?"

Our results also raise a caveat: "Packing" trauma exposure risk factors into dimensions based on an incorrect assumption regarding their causal origin (i.e., indicator homogeneity) may undermine efforts to "unpack" and clarify their differential relations with their respective causal consequences. Understanding that inter-item covariances *reflect event co-occurrences, not item homogeneity*, is the key to interpreting our puzzling results: The inverse loadings of *mother killed* and *sibling killed* on *Expulsion & Displacement* (Factor 2) reflect the grim strategy of ethnic cleansing—to frighten "undesirable" ethnic groups into fleeing a region by killing those who remain behind. The inverse loading of *left country because of the war* on *Siege* (Factor 1) reflects the difficulties inherent in escaping a siege. The failure of *father killed* to load any factor reflects the widespread conscription of fathers, who were exposed to lethal risks at the front lines that were largely independent of the risks to which their wives and children were exposed. Thus, a serious model–application mismatch may arise when the "real-world" structure among event types is incompatible with the assumptions of indicator homogeneity and of indices often used to gauge homogeneity (e.g., alpha; see Sijtsma, 2009). Although dropping inversely loaded items may drive up estimates of "internal consistency," it reduces test validity by reducing the correspondence between the test and the structure among variables it purports to measure (Borsboom et al., 2003, 2004). These results illustrate how complex patterns of "real-life" nonhomogeneous events can generate complex factor structures that faithfully mirror them (e.g., *Expulsion & Displacement* reflects both being driven from one's home and having one's mother and siblings *not* killed).

Question 2: Are some types of trauma exposure more potent causal risk factors than others, and if so, can they be prioritized? Table 3 illustrates the potential utility of effects decomposition via SEM for identifying who is at risk, for what outcomes, via which pathways. It is striking that all high-ranking risk factors consisted of events (life threat, traumatic death) consistently identified as traumatogenic (La Greca et al., 2002). These findings suggest that different types of trauma and loss "specialize," to a meaningful extent, in the types of risks they convey and the pathways through which they transmit their effects, permitting them to be ranked by total effect in reference to focal outcomes. This differentiation-focused method may help the field move beyond identifying "at-risk" individuals using ambiguous general markers of risk (APA Presidential Task Force, 2008) to instead stratifying them according to their risks for specific outcomes given their exposures to specific risk factors.

Question 3: How can we build our knowledge base in ways that help us develop risk assessment tools that can accurately predict who will need what types of help, across diverse settings and traumatic events? The composite-based method may hold three important advantages over the common factor approach for theory building and intervention applications. First, it promotes the construction of content-valid assessment instruments *that are tailored to specific settings* because its aim is to capture a census rather than a "best internally consistent sample" of trauma exposure. Second, it unpacks settings into *common denominator constructs* (e.g., life threat, traumatic death) that are more likely to be consistent in their composition and causal effects across diverse settings than event-specific variables (e.g., *Siege*). "Packaging" concepts at the more abstract level of *dimensions of trauma types* enhances the transportability of variables, measures, and findings across diverse settings (APA, 2008). Thus, one does not typically import (at least unmodified) measures across settings but rather, a general conceptual framework of exposure dimensions to serve as a test construction template. "Event tailoring" an exposure measure is guided by a two-step algorithm: *(a) Did exposure to a dimension (e.g., life threat) occur? (b) If yes, how was it manifest in this setting? Generate or modify as many items as needed* (e.g., using qualitative rapid needs assessment; see Betancourt, Speelman, Onyango, & Bolton, 2009) *to maximize content, construct, and ecological validity*. Third, "packaging" findings across studies into a common currency of exposure dimensions will help the field learn more efficiently across diverse events by facilitating cross-pollinating discourse between subliteratures (e.g., war, terrorism, hurricanes) that have been unnecessarily compartmentalized by setting-specific, event-bound measures and variables (La Greca et al., 2002). This will increase the growth rate, generalizability, and practical utility of the knowledge base while permitting meta-analytic studies that treat event type or setting as a moderator (e.g., life threat during torture or rape may be more traumatogenic, or may produce more distressing secondary adversities or trauma reminders, than life threat during a hurricane; Norris et al., 2006).

Question 4: How can these methods promote the study of development in high-risk settings? Findings that prewar trauma exerted direct predictive effects 5 years postwar underscores the potency of adverse childhood events in even highly stressful contexts, and suggests that *when* traumatic events occur may be as consequential as *what* occurs. Moreover, the complementary strengths of the common factor and composite-based models suggest that both models, used in tandem, can "unpack" complex events and their aftermath (Coltman, Devinney, Midgley, & Venaik, 2008). Examples include *unpacking risk factor caravans* and *resource caravans*. These caravans respectively consist of clusters of co-occurring risk and promotive/protective factors (e.g., social support) that "travel" with their host across development (Layne, Beck, et al., 2009). The common factor and related methods are well suited to unpack configurations of risk factors and resources that co-occur within and across developmental stages. Conversely, the composite approach is better suited to unpack the differential relations between individual caravan elements and their respective consequences. Such a dual-pronged approach can support not only secondary and tertiary interventions that seek to reduce psychopathology and dysfunction, but also strength-based public health approaches that emphasize prevention and positive development through the orchestration of resource gain cycles. This dual approach can also help to disentangle both the complex array of risk factors theorized to *cause* developmental trauma disorder—a constellation of cognitive, affective, somatic, and behavioral problems now under consideration for *DSM–V* (Courtois & Gold, 2009)—as well as its structure. The composite model broadly applies (Dodge et al., 2008): "Latent" sieges are no more a *cause* of shelling youth than physical abuse causes beatings, emotional abuse causes screaming, and community violence causes stabbings.

The common factor and composite methods can also be used to study differential risks for exposure to types of trauma as a function of developmental stage. Because adolescents often gather supplies in war settings and have social networks populated with peers and adult friends (Layne, Warren, et al., 2009), they may be at higher risk than children for many types of exposure, including life threat, witnessing injury or death, and having a close friend killed or injured. In contrast, children and adolescents may be at equivalent risk for loss of a parent. Differences in child versus adolescent reactions to war exposure may thus reflect differential exposure *to* specific types of trauma, differential effects *of* those exposures, and maturational and other contextual effects (Pat-Horenczyk et al., 2009; Pynoos et al., 1995; Shaw, 2003).

Question 5: How can these findings improve assessment and intervention? The limited utility of the common factor model for clinical applications is illustrated by the question, "What does knowing that siege exposure is the primary risk factor for every outcome really tell us about how to help war-exposed youth?" *Co-occurring* risk factors (e.g., all indicators loading *Siege*) are risk markers for one another, and for general "at risk" status (APA Presidential Task Force, 2008); thus, they help to identify *who may need help*. However, such risk markers provide very little guidance regarding *how, where, when, and why to help*. To the extent that it disperses equifinal risk factors (e.g., types of traumatic death) across different test dimensions, aggregates causally diverse risk factors into the same dimension (e.g., *Siege*), or drops "uncooperative" critical items (e.g., *father killed*), the common factor method can undermine assessment in four ways. First, causally complex exposure dimensions are ambiguous: Clinicians do not diagnose or treat clients for siege exposure per se. Such "risk factors" are too complex and vague in their makeup to serve any purpose other than general "markers of risk" (APA Presidential Task Force, 2008). Second, ambiguous test scores increase the risk for false negatives and false positives (Kraemer et al., 1999): A youth who is devastated by witnessing his father's death may score 3 on a war exposure inventory (and be overlooked), whereas a youth exposed to many less severe events may score 10. Third, because its "data input" is the structure of covariances *among risk factors*, the common factor model can create "context-specific" variables (e.g., *Siege*) and tests that reflect idiosyncratic ways in which risk factors co-occurred within a given setting and that have limited transportability across settings (APA Presidential Task Force, 2008).

A fourth problem is that causally diverse variables dilute, blur, and obscure, rather than clarify, differential relations between causes and consequences. *Siege Exposure* is the primary risk factor for all outcomes in this study *precisely because it is a complex composite of risk factors (or risk markers) for all outcomes.* Our capacity to accurately predict who will need services (APA Presidential Task Force, 2008) hinges on our ability to differentiate between the potencies, pathways of influence, and consequences of specific causal risk factors. Failure to discriminate adversely affects all "downstream" activities that require knowledge of *who is at risk for what outcomes via which pathways of influence* to make good evidence-based clinical decisions. Models in which most risk factors relate indiscriminately to most outcomes make elimination of *nonsignificant* pathways difficult. This reduction in model parsimony can both increase false-negative rates (by not ruling out those *not* at high risk for specific outcomes) and reduce efficiency (as specialized treatment components are assigned unnecessarily). For example, our results suggest that siege-exposed youths are at highest risk for all outcomes and thus are of higher priority than all other groups and should receive broad-spectrum treatments targeting all outcomes.

In contrast, better differentiated composite–causal indicator models may promote cost-effective, public health-based interventions (Layne, Beck, et al., 2009). Because subgroups most likely need services for those outcomes for which their types of exposure place them at risk, differentiated models can balance the *level of need* (groups at higher risk receive more specialized services), *effectiveness* (necessary services are provided), and *efficiency* (no unnecessary specialized services are provided). Differentiated models help to identify the specific types of trauma and loss that exert the greatest causal influence on each outcome and their respective pathways of influence. This knowledge will shed much-needed light on the key determinants of the clinical course of postwar distress and help to identify, prioritize, and triage youths and families to components that target their difficulties. A major advantage of differentiated models is their capacity to identify *"high-value" targets for intervention within the broader social and physical ecology in ways that facilitate assessment-driven, theoretically grounded, and evidence-based treatment tailoring at the individual case level.* Such an approach will encourage wellness, prevention, and intervention efforts that systematically address youth's specific life circumstances (e.g., orchestrating personal resource gain cycles to build "stress resistance-enhancing" resource caravans) rather than assigning treatment components to individuals solely on the basis of clinical cutoff scores on "end point" distress and dysfunction measures (Layne, Beck, et al., 2009). Subgroups exposed only to "indirect effect" (fully mediated) types of trauma may receive substantial and perhaps sufficient benefit from supportive skills-based components that interrupt key mediators and mitigate key moderators (Layne et al., 2007). Evidence that existential adversities (financial hardships) and trauma reminders (destroyed buildings) mediate the links between war exposure and postwar distress blurs the traditional distinction between "material" versus "psychosocial" postwar interventions: Rebuilding infrastructure to improve access to basic necessities, employment, housing, and schools is also a potent psychosocial intervention—a major added benefit for the same investment (Miller & Rasmussen, 2010). Further, evidence that highly traumatogenic events exert both indirect *and* direct effects suggests ways to introduce supplemental specialized components for high-risk groups for which mediator-focused interventions may be insufficient. For example, Trauma and Grief Component Therapy (Layne et al., 2008) is a multitiered school-based intervention that includes "Tier 1" classroom components targeting key mediators (e.g., coping with trauma reminders) and moderators (e.g., recruiting social support), and "Tier 2" group-based components targeting highly traumatogenic events (trauma and grief processing). A program evaluation (Cox et al., 2007; Layne et al., 2008) found that Tier 1 components were widely disseminated at low cost, producing substantial benefit with low iatrogenic risk. The Tier 2 condition produced improvement rates comparable to rigorously controlled treatment efficacy trials.

Study Limitations

This study used a self-report screening index of life events (Monroe, 2008) and did not include measures of loss reminders (a theorized mediator; Layne et al., 2006) and grief reactions; both measures are included in a forthcoming study. The cross-sectional retrospective design precludes both causal inference (as event reporting may be confounded with current psychological functioning) and the longitudinal analysis of adjustment trajectories (Layne, Beck, et al., 2009). The extended time frame (5 years postwar) created a window in which other risk factors (especially postwar trauma) could occur and compete for explained variance, allowing perhaps only the most traumatogenic or impactful war-time risk factors to exert significant predictive effects. The time frame also sampled youths 8–14 years old at the *end* of the war—a group less likely to be severely exposed than older adolescents. This may have led to low endorsement rates for some event types (e.g., physical injury) that prevented their predictive effects from being adequately tested. In addition, the purposive sampling of classes with a high prevalence of severely war-exposed students limits the generalizability of findings to more severely exposed youths residing in the region. Moreover, the variance decomposition method used to rank risk factors assumes that all nontrivial variables are included in the model; omitting influential variables may alter parameter estimates and risk factor rankings (Byrne, 2001). Further study is also needed to evaluate the divergence in performance between the two approaches, as well as the generalizability and utility of the eight-dimensional framework used in the composite approach, in other settings and applications. Last, although evidence for its utility is accumulating (Coltman et al., 2008), critics (e.g., Wilcox et al., 2008) question the applicability of the composite model; for example, different research teams could produce different sets of indicators purporting to measure the same composite. We concur that this is possible but assert that the caveat applies with equal force to the common factor model, which may produce "researcher-idiosyncratic" discrepancies arising from item wordings, guiding theory, and so forth.

Sierra Leone's Former Child Soldiers: A Follow-Up Study of Psychosocial Adjustment and Community Reintegration

This is the first prospective study to investigate psychosocial adjustment in male and female former child soldiers (ages 10–18; $n = 156$, 12% female). The study began in Sierra Leone in 2002 and was designed to examine both risk and protective factors in psychosocial adjustment. Over the 2-year period of follow-up, youth who had wounded or killed others during the war demonstrated increases in hostility. Youth who survived rape not only had higher levels of anxiety and hostility but also demonstrated greater confidence and prosocial attitudes at follow-up. Of the potential protective resources examined, improved community acceptance was associated with reduced depression at follow-up and improved confidence and prosocial attitudes regardless of levels of violence exposure. Retention in school was also associated with greater prosocial attitudes.

At present, Sierra Leone is still contending with the legacy of the 1991–2002 civil conflict involving the Revolutionary United Front (RUF), the Sierra Leonean Armed Forces Revolutionary Council (AFRC), the Sierra Leone Army, and local groups like the Civil Defense Forces (CDF). This bloody civil war led to human rights abuses, including mass mutilations and the pervasive use of children in armed conflict. Thousands of children, some as young as 7 years old, were conscripted into fighting

---

We are endlessly grateful to all the local research assistants who carried out these interviews in Sierra Leone and our field-based project coordinators, Moses Zombo and Nassrin Farzaneh, who supervised the teams in 2002 and 2004. We are extremely indebted to Lloyd Feinburg, John Williamson, and Cathy Savino of USAID's Displaced Children and Orphans Fund (DCOF). In addition, we are grateful to our colleagues at the International Rescue Committee, including Jane Warburton, Jodi Nelson, and many others who helped this project to succeed along the way. In particular, we would like to thank Catherine Weisner whose leadership was essential for launching the first wave of data collection. We would like to thank Laura Nolan, Kate Ittleman, and Harlyn Sidhu who helped compile and prepare the tables presented in this article and Julia Rubin-Smith who coordinated our Boston-based team. We would also like to thank Dr. Maggie Alegria of Harvard Medical School for her review of previous versions of this article, Dr. Garrett Fitzmaurice of McLean Hospital for his excellent statistical advice, and Sidney Atwood and Kathy McGaffigan for their tremendous skill in data management and analyses. This work was funded by USAID's Displaced Children and Orphan's Fund. The present publication was also supported by Grant 1K01MH077246-01A2 from the National Institute of Mental Health and Grant P60 MD002261 from the National Center for Minority Health and Disparities.

forces and paramilitary groups (Betancourt, Simmons, et al., 2008; The World Revolution, 2001). Many young boys and girls were brutalized into submission, drugged, and then forced to fight on the frontlines of combat; others who did not fight served as porters, cooks, guards, messengers, servants, human shields, or bush "wives." Although most point to abduction as their point of entry into their role as child soldiers (Mazurana & Carlson, 2004), some children may have assumed a more active role in their decision to participate in armed conflict. The breakdown of family and community systems, coupled with insufficient educational opportunities, left many children with limited viable options for the future (Ashby, 2002). Consequently, a militia group's promise of adventure, security, and camaraderie led some to turn to conscription into armed conflict as their "best among the worst" of options (Machel, 2001; Peters & Richards, 1998; Shepler, 2005). As a result of their involvement with armed forces and armed groups, many youth were witnesses and/or perpetrators of intense physical violence, including summary executions and death-squad killings, torture, detention, rape, bombings, forced displacement, destruction of homes, and massacres of family members. They were deprived of their rights to the care and protection of their families, and denied education and other developmental opportunities.

The Sierra Leone conflict involved direct attempts by rebel groups to destroy relations between young abductees and their families and communities. This was done by forcing many young people to commit atrocities (killings, assault) against loved ones and neighbors under the threat of death. This violent indoctrination into fighting forces was intended to sever ties that might lead abducted youth to attempt escape and return home (Betancourt, Pochan, & de la Soudiere, 2005; Wessells, 2005). Nevertheless, with the signing of the Abuja agreements in November 2000 and May 2001, most of Sierra Leone's former child soldiers began a long journey of return to their families and communities.

Disarmament, demobilization, and reintegration (DDR) refers to the process by which soldiers are returned to civilian life as conflicts end. DDR programs aimed specifically at child soldiers have been established in several countries, including Sierra Leone, where the National Center for DDR implemented a program of demobilization in conjunction with the United Nations Mission in Sierra Leone (UNAMSIL) and the warring parties (RUF, CDF, AFRC). These activities resulted in the demobilization of more than 72,000 combatants—including over 6,700 boys and girls—across the country (National Committee for Demobilisation Disarmament and Reintegration, 2004; United Nations International Children's Emergency Fund, 2005).

The first step in DDR, disarmament, involves soldiers turning in their weapons, which are usually destroyed. The second step, demobilization, involves disbanding armed groups and releasing former child soldiers into civilian society. This step often includes family tracing in order to identify remaining family members or potential alternate caregivers for returning youth. The third phase, reintegration, is a much longer and more complex process. It is in this phase that psychosocial issues take center stage. Given direct attempts by armed forces to destroy relationships between abducted children and their families and communities, social reintegration remains a challenging issue in post-conflict Sierra Leone. To facilitate this process, sensitization campaigns were implemented to initiate local discussions about the reintegration of former child soldiers in the community. In addition, upon reunification, efforts were made to place children back into intact families, particularly families involving biological relatives (Betancourt, Pochan, et al., 2005; Williamson, 2005). Although many organizations identified and trained community volunteers to provide monitoring and individual follow-up of resettled former child soldiers, no formal research has examined the social reintegration and psychosocial adjustment of these youth over time. This study is intended to address these gaps.

Child Soldiers: A Global View

Despite a near universal condemnation from the international community (United Nations International Children's Emergency Fund, 2003), the use of child soldiers remains an ongoing reality in many modern armed conflicts. The 2008 Child Soldiers Global Report documents the abduction and forceful conscription of children (both boys and girls) into government forces and armed groups in at least 86 countries to date (Coalition to Stop the Use of Child Soldiers, 2008). Since 2001, conflicts in Africa have involved the conscription of children into armed forces and armed groups including wars in Angola, Burundi, the Central African Republic, Chad, Cote d'Ivoire, the Democratic Republic of Congo, Guinea, Liberia, Rwanda, Sierra Leone, Somalia, and northern Uganda (Coalition to Stop the Use of Child Soldiers, 2004, 2008).

Child soldiers include boys and girls, many of whom are not fighters but are used in other ways.

For these reasons, the 2007 Paris Principles established the definition of a child associated with an armed force or armed group as "any person below 18 years of age who is or who has been recruited or used by an armed force or armed group in any capacity, including but not limited to children, boys and girls, used as fighters, cooks, porters, messengers, spies or for sexual purposes. It does not only refer to a child who is taking or has taken a direct part in hostilities" (United Nations International Children's Emergency Fund, 2007, p. 7). The Paris Principles and other policy efforts have illuminated the child protection and rehabilitation issues central to addressing the problem of child soldiers globally. Experts contend that the term *children associated with armed forces and armed groups* (CAAFAG) is more accurate and captures the realities faced by children involved with armed groups and armed forces far beyond the proportion who actually engage as combatants (Betancourt, Borisova, et al., 2008). For the purposes of the present study, we use the term *child soldier* for ease of readability with the caveat that we are implying the broader view involved in the use of the term *CAAFAG*.

Psychosocial Adjustment and Social Reintegration of Former Child Soldiers

Although the research on this topic is scant, war-related exposures and unsuccessful transitions into civilian life are thought to place former child soldiers at increased risk of mental health problems, re-recruitment, and many other forms of exploitation (Betancourt, Borisova, et al., 2008; Betancourt, Pochan, et al., 2005; Eyber & Ager, 2003). Using various measures of psychosocial well-being and mental health, a handful of cross-sectional studies with former child soldiers have reported high levels of psychosocial problems relatively soon after reintegration. For instance, Allen and Schomerus (2006) collected data on a large ($n = 886$) sample of former child soldiers under 18 years in Uganda who had recently reintegrated into their communities. Although the study did not use standardized measures of mental health outcomes, high levels of psychological trauma and social difficulties were reported. Using the Impact of Event Scale–Revised (Weiss & Marmar, 1997), Derluyn, Broekaert, Schuyten, and De Temmerman (2004) documented high levels of symptoms (97%) of posttraumatic stress disorder (PTSD) among 71 former child soldiers in northern Uganda. Among Ugandan and Congolese former child soldiers ($n = 169$), Bayer, Klasen, and Adam (2007) found that more than one third (34.9%) met diagnostic criteria for PTSD. Similarly, Kohrt's (2007) study in Nepal found that children associated with fighting forces exhibited moderately higher psychosocial problems (aggression, depression, anxiety, and posttraumatic stress) when compared with never-associated children.

However, not all studies of former child soldiers document high rates of mental distress or disorders. For instance, Annan, Blattman, and Horton's (2006) Survey of War-Affected Youth (SWAY) in northern Uganda indicated that despite high rates of exposure to violence among male former child soldiers, levels of emotional distress were lower than might otherwise be expected. When compared with children never abducted by fighting forces, psychological problems among returning former child soldiers appeared mild to moderate, with serious distress concentrated in the minority of participants who experienced extreme violence (including perpetration of violence). In addition, the correlation between abduction and aggression was weak or nonexistent (Blattman & Annan, 2007). Using retrospective reports, the SWAY study team found that even though some formerly abducted females reported difficulties with family and community acceptance upon return, a majority reported increased acceptance over time. The authors concluded that abduction itself was generally not a good predictor of mental health problems (Annan, Blattman, Carlson, & Mazurana, 2008).

The studies of former child soldiers reviewed earlier involved data collection on samples relatively soon after demobilization or immediately following community reintegration. Only a handful of studies have assessed mental health and psychosocial functioning over time, addressing the potential long-term psychological consequences of involvement in armed forces and armed groups. Santacruz and Arana (2002) interviewed 239 former child soldiers, who had belonged to armed groups in El Salvador, nearly 10 years after the end of its civil war. At the time of these interviews, a majority of the sample continued to have vivid memories of war-related violence. Twenty percent suffered from constant insomnia and 16% reported persistent nightmares. In addition, 39% said that they felt tired and depressed quite often, 39% reported problems with nervousness, and 37% said they were easily annoyed and angered. This study highlights the potentially enduring difficulties faced by adults who were associated with armed groups as children.

To date, only one prospective longitudinal study of former child soldiers is available in the published literature. Boothby and colleagues followed a small cohort of male former child soldiers from Mozambique over a period of 16 years and outlined some of the long-term effects of child involvement with armed groups (Boothby, Crawford, & Halperin, 2006). Overall, the results of this research suggest that a majority of the 39 young men studied made significant progress in returning to civilian life. However, none were able to fully escape their violent pasts. In 1988, while at the Lhanguene Rehabilitation Center in Mozambique, each young man in the sample reported experiencing recurrent thoughts and memories of traumatic events. Overall, symptoms of distress persisted 16 years later, but the proportion of former child soldiers experiencing problems as adults was considerably lower than those reporting these problems as children (Boothby, 2006). At the last point of assessment, 50% of the participants reported emotional and physical reactions or symptoms indicative of traumatic stress reactions when reminded of hurtful or traumatic events. Additionally, the research indicated that longer length of time spent in the captivity of fighting forces seemed to augment risk of poor long-term social and emotional adjustment (Boothby, 2006). Although the small sample size ($n = 39$) of this study does not allow for in-depth statistical analyses, it does provide an important perspective into the long-term psychosocial consequences of child soldiering.

Former Child Soldiers: An Interactive View of Resilience

One of the questions of greatest interest regarding the well-being of former child soldiers is: How do these youth fare over time? Some surrender to the notion that these youth are a ''lost generation,'' essentially too disturbed and violent to function productively. Some, however, think these youth may represent a subset of resilient individuals who drew from personal strengths and external supports to survive a harrowing experience. A resilience perspective (Layne, Warren, Watson, & Shalev, 2007; Masten & Obradovic, 2008; Rutter, 2006) provides a complex and integrated conceptual framework for thinking about posttraumatic adaptation in former child soldiers over time. Resilience is regarded as an interactive concept referring to ''a relative resistance to environmental risk experiences, or the overcoming of stress or adversity'' (Rutter, 2006). The traumatic stress literature provides an integrative perspective on resilience and adaptation that is helpful for understanding the mental health of young people exposed to acute traumatic events such as armed conflict (Layne et al., 2007). Within the overarching framework of resilience, theories of *stress accumulation* and *stress adjustment* offer complementary views for understanding former child soldiers' response to the compounded adversity characterizing their experience.

Theories of *stress accumulation* posit that the risk for poor mental health and developmental outcomes rises markedly with the accumulation of adverse life experiences (Dohrenwend & Dohrenwend, 1974; Lazarus & Folkman, 1984; Rutter, Pickles, Murray, & Eaves, 2001; Thoits, 1991). A stress accumulation model suggests that children are profoundly affected through repeated and prolonged exposure to severe trauma or a series of stressful events that exceed an individual's threshold level of stress. Such exposure to stressful events can lead to a prolonged activation of biologically based coping strategies that, when repeatedly activated, may compromise individuals' capacity to readjust, leaving them increasingly susceptible to physical or psychological problems throughout the life course (Dohrenwend & Dohrenwend, 1974; McEwen, 2000; Worthman & Panter-Brick, 2008). Particularly, when these events occur early in life, the accumulation of such chronic or ''toxic stressors'' (National Scientific Council on the Developing Child, 2005) may limit the degree to which protective processes may be able to offset exposure to repetitive adversity (Beckett et al., 2006; Nelson et al., 2007; Smyke et al., 2007).

Resilience research has documented a number of protective processes that can help children achieve good functioning, despite exposure to a range of difficult life circumstances (Luthar & Goldstein, 2004). The *stress adjustment paradigm* (Lazarus & Folkman, 1984) emphasizes the role of individual, familial, and community resources in understanding the relation between adverse life events, stressors, and subsequent psychological adjustment and adaptation (Masten & Obradovic, 2008). According to this framework, trauma, psychological adjustment, resilience, and the mental health of former child soldiers must be viewed as a dynamic process involving a number of ecological levels offering potential sources of protection (Bronfenbrenner, 1979) rather than solely individual characteristics (Betancourt & Khan, 2008; Lazarus & Folkman, 1984; Masten & Obradovic, 2008).

Resilience theory and, within it, theories of stress accumulation and stress adjustment direct us to consider the complex interplay of risk and protective processes (Rutter, 2006), both during and after conflict, that likely shape the psychosocial outcomes and adjustment trajectories of former child soldiers. Young people associated with fighting forces may differ with regard to the frequency, duration, and severity of their war experiences, as well as the accumulation of war-related stressors they experienced. Former child soldiers may also differ with regard to their postwar situations, particularly in terms of the family and community supports and resources available to them. Therefore, it is important to consider the accumulation and combination of both risk and protective factors in the lives of former child soldiers to better understand their long-term psychosocial adjustment (Betancourt, Borisova, et al., 2008; Wessells, 2006).

On the basis of the existing evidence cited earlier, we are able to develop hypotheses regarding the influences of specific war-related exposures and potential postconflict protective factors on the psychosocial well-being of former child soldiers. Exposure to violence is the most common risk during wartime (Annan et al., 2006; Bayer et al., 2007; Kohrt et al., 2008). Although most children affected by war experience high rates of exposure to violence (Barenbaum, Ruchkin, & Schwab-Stone, 2004; Lustig et al., 2004), child soldiers are distinguished by experiencing particularly toxic forms of violence, often involving repeated personal victimization and in the most extreme cases, being forced to kill others (Coalition to Stop the Use of Child Soldiers, 2008). For example, in northern Uganda, Derluyn et al. (2004) observed very high rates of violent experiences with a majority of the sample reporting exposure to more than six traumatic events. Seventy-seven percent of the sample reported witnessing the killing of others, 35% reported sexual abuse, and 39% of the sample reporting having wounded or killed others.

Gender is an important factor shaping the war experiences of children associated with armed forces and armed groups. Females comprise a significant proportion of children involved with armed groups globally (McKay & Mazurana, 2004). Although rape occurs among both male and female child soldiers (Annan et al., 2008; Betancourt, Borisova, et al., 2008; Johnson et al., 2008; McKay & Mazurana, 2004), sexual victimization presents particular challenges for psychosocial adjustment and social reintegration as female former child soldiers may be viewed as sexually impure or promiscuous (Betancourt, Borisova, et al., 2008; Burman & McKay, 2007; Coalition to Stop the Use of Child Soldiers, 2008; Mazurana & Carlson, 2006; Mazurana & McKay, 2003; McKay & Mazurana, 2004; McKay, Robinson, Gonsalves, & Worthen, 2006).

Furthermore, prior research has indicated that the length of time that a young person spends with armed groups may place them at greater risk for an accumulation of violence exposures as well as social and material deprivation (Betancourt, Borisova, et al., 2008; Coalition to Stop the Use of Child Soldiers, 2008).

Sources of potential protection have also been documented in research on war-affected youth (Barenbaum et al., 2004; Betancourt & Khan, 2008; Lustig et al., 2004). For child soldiers, acceptance from family members, peers, and others in the community has been indicated as an important postconflict determinant of psychosocial adjustment (Betancourt, Borisova, et al., 2008; Betancourt, Simmons, et al., 2008). For example, Annan et al. (2006) found that male former child soldiers reporting higher levels of family connectedness were likely to have lower levels of emotional distress and better social functioning. In some settings, community members may be open to accepting a child back, despite his or her involvement with armed groups. In other situations, community members may view former child soldiers with fear and distrust due to atrocities committed during war time (Annan et al., 2006; Santacruz & Arana, 2002). In Sierra Leone, despite sensitization campaigns in villages, a widespread initial community response was fear toward the returned child soldiers (Betancourt, Simmons, et al., 2008). Collectively, these studies suggest that the degree to which community acceptance changes over time plays an important ameliorative role for children at risk for poor adjustment given severe forms of war exposure.

Finally, sustained access to education remains an important consideration for the well-being of former child soldiers (Betancourt, Simmons, et al., 2008; Machel, 1996). Opportunities to develop literacy and economic skills can aid in social reintegration of returning children and may act as a deterrent against re-recruitment (Alexander, 2006; Betancourt, Brewer, & De la Soudiere, 2005; Sommers, 2003; Williamson, 2005). Schools may also serve as an important place to build positive social ties and a source of predictability in the lives of war-affected youth (Betancourt, 2005; Sommers, 2003). In this manner, it is possible that children with consistent school access may demonstrate improved psychosocial adjustment.

Study Aims

This study reports on the baseline and follow-up phases of a longitudinal study of former child soldiers in Sierra Leone. Consistent with a stress-accumulation approach, we hypothesized that psychosocial adjustment among former child soldiers would be associated with the degree of exposure to war violence, with the most detrimental effects among groups exposed to severe events (rape and wounding or killing others). In examining hypotheses about stress adjustment, we also hypothesized that the presence of protective factors related to the individual (school access), family (family acceptance), and community (community acceptance) would be associated with improved psychosocial adjustment at follow-up. We anticipated that the presence of protective factors indicative of social acceptance (family and community acceptance) would lead to better psychosocial outcomes, particularly among youth exposed to potentially stigmatizing war experiences (e.g., rape, wounding or killing others).

Method

Participants and Procedures

This investigation was conducted in collaboration with the International Rescue Committee (IRC). Data collection began in 2002 with a baseline assessment (Time 1 [T10]) of 260 former child soldiers who had been affiliated with the RUF in Sierra Leone. At the time, the IRC was a lead agency supporting DDR in several parts of the country. The initial sample for the study was obtained using a two-stage method of selection. First, IRC registries were pooled to create a master list of all youth who had been processed through Interim Care Centers at all sites in four districts of Sierra Leone during the most active period of demobilization, from June 2001 to February 2002 ($n = 309$). All participants were between the ages of 10 and 18 at the time of selection and had been involved with the RUF's fighting forces. Exclusion criteria included inability to be interviewed due to a severe cognitive or physical disability as reported by program social workers (although no such cases were identified) and/or not falling within the target age range.

At follow-up in 2004 (Time 2 [T2]), 56.5% of the original sample was reinterviewed ($n = 156$). Midway through T2 data collection, the death of the IRC's country director and subsequent suspension of program activities halted completion of the follow-up survey. As a result, 31% of the original sample was not recontacted for follow-up. Of those T1 participants attempted for interviews at T2, 1% of caregivers declined consent for their child to participate, 1% of participants had died, and 7% of the initial sample had relocated at a distance that prevented follow-up. Participants lost to follow-up did not differ significantly from ongoing participants in terms of age ($p = .74$), gender ratio ($p = .60$), or literacy levels ($p = .48$). Higher percentages of completers versus noncompleters (71% vs. 53%) attended school at baseline ($p = .002$). Participants lost to follow-up reported similar levels of community acceptance at T1 ($p = .63$). Ongoing participants did not differ from those lost to follow-up on depression ($p = .12$), anxiety ($p = .29$), hostility ($p = .14$), prosocial attitudes ($p = .32$), or confidence ($p = .96$) as assessed at baseline. No significant differences were found between noncompleters and ongoing participants in terms of age of abduction ($p = .19$) or length of time with the fighting forces ($p = .45$).

Data for all participants at T1 and T2 were collected through face-to-face interviews by a team of seven trained Sierra Leonean research assistants, monitored by the study PI and IRC staff at the country level. All research staff participated in a 4-day training on interviewing procedures and ethical practices in working with vulnerable populations. The Sierra Leonean local research team and the study principal investigator determined a process to best introduce the research to the community in a manner respectful of cultural norms about decision making. First, the process of consent involved contact with village leaders and neighborhood meetings to introduce and explain the research. Second, local research assistants traveled to the target households with an IRC staff member. The study was then introduced and any questions answered in the local language, Krio, before a signature was given. All instructions, consents, and assents were read aloud. Participants were informed of the general intent of the study and its longitudinal nature, including the intent to contact participants for future interviews. The youth-informed assent process was conducted separately from the parent- or guardian-informed consent.

Due to a low literacy rate in the study population (50%), all survey protocols were administered verbally. The survey instrument, recruitment materials, and the informed consent forms were constructed for easy comprehension and brevity. Visual aids were used to assist in the administration of Likert-type scales. The T1 assessments were approved by the IRC country program and headquarters staff; the T2 survey received Institutional Review Board approval from Boston University School of Medicine and Boston Medical Center where the first author was based at the time. At baseline and follow-up, IRC social workers traveled with the research team to respond to cases requiring additional attention due to severe emotional or physical health needs.

In non-Western contexts, such as Sierra Leone, the cultural validity of constructs measured remains a perennial challenge for cross-cultural research (Achenbach & Rescorla, 2006; Canino & Alegria, 2008). For these reasons, many of our measurement scales were developed in close consultation with local staff as well as focus group discussions among youth similar to the study population to determine the face validity and cultural relevance of survey items. All measures and questions were then forward- and back-translated to ensure accuracy. Similar combined methods for cross-cultural instrument development have been used in several recent studies of psychosocial adjustment of former child soldiers (Bayer et al., 2007; Kohrt et al., 2008).

This study reports results for the sample of $n = 156$ youth who were contacted at both the T1 and T2 waves of data collection. The average age at T1 in this sample of former child soldiers was 15.13 years, with 12% female and 88% male participants (Table 1). The sample was almost equally split in terms of religious background (53% Christian and 47% Muslim). At T1, 50% of the sample reported poor literacy skills (reading and writing), with similar percentages of both girls and boys reporting poor literacy (53% of girls and 50% of boys); 72% of the youth were attending school at baseline; and 65% were in school at the time of both interviews. At T1, the majority (83%) of the youth reported staying with an immediate family member whereas 17% reported staying with an extended family or other caretaker; 84% of the female and 55% of the male caretakers were illiterate and reported no educational background.

Table 1
Sociodemographic Characteristics of the Sample

Characteristic	*M/N* (*SD*/%)
Age at interview T1, years	15.13 (2.25)
Sex[a]	
Male	137 (88%)
Religion, T1	
Christian	79 (53%)
Muslim	70 (47%)
Literacy, T1	
Poor	73 (50%)
Functional	57 (40%)
Moderate	15 (10%)
In school,[b] T1	107 (72%)
In school at T1 and T2[c]	96 (65%)
Age of abduction, years	10.51 (2.98)
Length of time with armed forces, years	4.68 (0.73)
Relative SES, T2 (range = 4–16)	9.39 (2.28)

Note. *N*s = 143–156.
[a]Coded 0 for boys and 1 for girls. [b]Coded 0 for youth who were not in school and 1 for youth who were in school. [c]Coded 0 for youth who were not in school at T1 or T2, and 1 for youth who were in school at both T1 and T2.

Measures

War experiences. To assess individual exposures to severe forms of war violence, we used items from the Child War Trauma Questionnaire (CWTQ; Macksoud & Aber, 1996), initially developed for use with Lebanese war-affected youth. The questionnaire was adapted by our research team to better capture the context of the war in Sierra Leone; for example, items on bombing and shelling were removed and items on sexual assault and being forced to kill others were added. The adapted instrument contained 42 items regarding child's experience of war-related events. War experiences were coded for occurrence versus no occurrence because some traumas were experienced so commonly that participants had a difficult time accurately recalling or assessing frequency.

Three types of war experiences were examined in light of theory and research on the psychosocial adjustment of former child soldiers: (a) *witnessing general war violence* (e.g., massacres or raids on villages), (b) *experiencing rape*, and (c) *participation in wounding or killing others*. We chose these categories because we were interested in exploring the particular effect of forms of severe violence common in former child soldiers. The survey instrument also included a self-reported age of abduction as well as duration of time with the fighting forces that were analyzed separately.

Retention in school. A variable indicative of sustained access to education was created by comparing youth who reported being in school at both T1 and T2 with youth who were not in school at one or both waves of data collection.

Family acceptance. A measure of family acceptance was drawn from our previous qualitative work and consultations with local staff in 2002. The measure, only administered at T2, consisted of six items assessing the way former child soldiers perceived acceptance, understanding, and respect from their family members. Items were scored on a Likert scale with response options of *not true*, *sometimes true*, or *very true*. Questions on this scale included "since the war you feel you are welcome in the family with whom you live," "you have the same opportunities and responsibilities as other children in the family (or household)," "your caregivers treat you as well as the other children in the household," and so on. This measure exhibited strong internal reliability (Cronbach's α = .93). At T2, reports of family acceptance were skewed toward high values. As a result, the scale was dichotomized for statistical analyses (see next).

Community acceptance. A measure of community acceptance was drawn from our qualitative work and consultations with local staff in 2002. The measure consisted of six items assessing the way former child soldiers perceived acceptance from others in the community. Items were scored on a Likert scale with response options of *not true* to *sometimes true* or *very true*. The measure included items such as "since the war, have people in this community been good to you?" "since the war, you feel you have been welcomed back into the community where you live," and so on. This measure was administered at both waves of data collection and exhibited strong internal reliability (Cronbach's α = .90 at T1 and Cronbach's α = .89 at T2). For each child, we computed a subscale score for community acceptance at T1 and T2. We also computed a "change in acceptance" by subtracting the T1 score from the score at T2. An increase in the community acceptance score between baseline and follow-up would thus indicate a positive change in community acceptance. Because change in community acceptance differed for those starting at higher or lower levels, all analyses were adjusted for T1 community acceptance.

Psychosocial adjustment. To assess psychosocial adjustment, we used a measure developed by researchers at the Oxford Refugee Studies Program (MacMullin & Loughry, 2004). This instrument was drawn from several standardized child mental health measures and was adapted for use among former child soldiers from Sierra Leone and northern Uganda using participatory methods (MacMullin & Loughry, 2004). The measure contains 52 items: three subscales for mental health problems (anxiety, depression, hostility) and two subscales for positive and adaptive adjustment outcomes (confidence and prosocial attitudes). Each of the five domains is represented by a set of questions that inquires about specific behaviors particular to that domain (e.g., "Do you cry easily?" [Depression], "Do you get into fights?" [Hostility], and "Do you share with others?" [Prosocial Attitudes]). For each question responses were scored on a 1–4 scale, ranging from 1 = *never*, 2 = *rarely*, 3 = *sometimes*, and 4 = *always*.

Following our experience with using this measure at T1 in 2002, three items were excluded from the measure when it was readministered at T2 in 2003–2004. Additionally, upon further analyses of T1 and T2 data, three more items were dropped because they did not contribute to the internal consistency of corresponding subscales. The 46-item version of this instrument had good internal consistency across all subscales at both waves of data collection. At follow-up, the Cronbach's α was .67 for the *anxiety subscale* (8 items), .70 for the *depression subscale* (8 items), .88 for the *hostility subscale* (12 items), .76 for the *prosocial attitudes subscale* (10 items), and .69 for the *confidence subscale* (8 items). For each child, we computed a subscale score (e.g., anxiety, depression, hostility, prosocial attitudes, and confidence) at T1 and T2.

Participant demographic characteristics. A demographic inventory collected information on gender, age, and family socioeconomic resources. The measure of socioeconomic status was created to indicate an individual's access to food, housing, and clothing relative to others in the community. The measure consisted of four items and had a good internal consistency (α = .78).

Statistical Analyses

Statistical analysis of the data proceeded in three stages. First, descriptive statistics of study variables were analyzed. Summary statistics for continuous measures are reported as mean and standard deviation, whereas dichotomous measures are reported as percentages along with their associated counts.

Multiple imputation was then used to generate five complete datasets for the 156 participants in the baseline and follow-up interviews (Rubin, 1987). All remaining analyses were conducted using the multiply imputed data sets, and results were combined across imputations. This approach reduces bias to the extent that values on the observed variables are informative about values on items that were missing, increases precision relative to a complete case analysis with a smaller N, and accounts for the sampling variability across imputations (Rubin, 1987). Imputed data sets were generated using the method of chained equations as implemented in *IVEware* (Raghunathan, Lepkowski, Van Hoewyk, & Solenberger, 2001) and the results of analyses conducted across imputations were combined using the MIANALYZE procedure using the SAS software system, version 9.1 (SAS Institute, 2004).

First, paired *t* tests were used to compare values for psychosocial adjustment at T1 compared to T2. Second, correlation coefficients were calculated between all variables in order to inspect unadjusted, bivariate associations. Third, multiple linear regression was used to assess the effect of predictors on T2 psychosocial outcomes after adjusting for T1 scores and potential confounders. For each psychosocial outcome (depression, anxiety, hostility, confidence, and prosocial attitudes), three main-effects regression models were fit, allowing assessment of the impact of introducing successive sets of covariates. The first model included only demographic factors (age, sex of child, socioeconomic status [SES]) and baseline psychosocial adjustment scores. In the second model, dichotomous war experiences were added to the model to test the effects of stress accumulation. Model 3 added protective factors to the model to test hypotheses regarding stress adjustment. At each step, we compared parameter estimates and model fits and calculated the difference in R^2.

After assessing the main effects models, we tested whether the inclusion of interaction terms improved the overall model fit. Interactions were examined in conceptual groups testing first interactions between war exposures and protective factors. A second group of interactions was then tested examining interactions between gender and risk factors and then gender and protective factors on psychosocial outcomes. An *F* test using the TEST command in PROC MIANALYZE (SAS Institute, 2004) was performed upon adding each conceptual group of interactions to the final main effects model (Model 3 for each outcome) to test the joint hypothesis that the combined effect of the interactions did not differ from zero. If the *F* test was nonsignificant, no further individual testing of interactions was conducted to reduce risk of chance findings. If the *F* test indicated that interactions in the conceptual group improved the overall model fit, individual interactions were tested by adding them one by one to the final model for each outcome.

All statistical analyses (two-tailed) were performed using the SAS software system, version 9.1 (SAS Institute, 2004).

Results

Exposure to Violence of Study Population

The average age at abduction in this sample of former child soldiers was 10.51 years with no significant difference between males and females. Twelve percent of participants reported joining the fighting forces at very young ages (2–5 years), which likely reflects the fact that some children may have been abducted while with their mothers in the bush. Average length of abduction was 4.68 years with males and females reporting a similar duration of time in captivity with armed forces (Table 1). Nearly all (99%) former child soldiers in the sample reported forced conscription (mainly through abduction).

All former child soldiers in the sample were exposed to high levels of violence. For example, 89% of females and 88% of males had witnessed some sort of war-related violence such as massacres or raids on villages. Being a victim of rape was reported by 37% of females and 6% of males in the sample. Perpetration of extreme acts of violence was reported by both males and females; 26% of females and 28% of males reported having killed either a stranger or loved one. Overall, 7% of youth reported experiencing all three exposures—witnessing mass violence, rape, and wounding or killing others.

Change in Psychosocial Outcomes

Table 2 reports the results of the baseline and follow-up assessments of each of the subscales on the measure of psychosocial adjustment. Average scores for the depression, hostility and anxiety subscales did not differ significantly between T1 and T2. In terms of the adaptive outcomes, confidence scores were similar between the two waves of assessment, yet average prosocial attitudes were lower at T2 compared with T1.

Predictors of Psychosocial Outcomes: Correlational Analysis

Bivariate correlations indicated expected patterns of covariation within and between variable domains (Table 3). The three subscales of mental health problems were positively intercorrelated as were the subscales for the two adaptive outcomes, confidence and prosocial attitudes ($r = .73$). Higher levels of prosocial attitudes and confidence at T2 were correlated with symptoms of anxiety ($r = .22$, and $r = .27$, respectively), but not other mental health problems.

Table 2
Psychosocial Adjustment Over Time

	Range	T1, *M* (*SD*)	T2, *M* (*SD*)	Change over time, *M* (*SD*)	*p* value[a]

$^{\dagger}p \leq .10$. $^{*}p \leq .05$. $^{**}p \leq .01$. $^{***}p \leq .001$.

Turning to cross-domain relations, we explored the relation between the adjustment outcomes and two sets of predictors: (a) war-related risk factors (endorsing general witnessing of war violence, experiencing rape, wounding/killing others, length of time with the RUF, and age of abduction) and (b) hypothesized protective factors (retention in school, community acceptance, family acceptance). Several of these variables were associated with T2 psychosocial outcomes.

War-related risk factors. Witnessing of general war-related violence was correlated with higher levels of hostility at T2 (*r* = .20). Being abducted at a younger age and length of time spent with the fighting forces were not significantly correlated with any of the outcomes investigated. Experiencing rape during the war was associated with higher levels of hostility at T2 (*r* = .49). In addition, rape was associated with higher levels of depression (*r* = .24) and anxiety (*r* = .38) at T2. Rape was also associated with higher levels of prosocial behaviors (*r* = .21) yet inversely correlated with staying in school (*r* = −.39) and family acceptance (*r* = −.28). Having killed someone during the war was associated with higher levels of depression ($r = .24$), anxiety ($r = .31$), and hostility ($r = .40$).

Protective factors. Of the protective factors examined, family and community acceptance demonstrated promise as important psychosocial resources for the youth in our sample. Family acceptance was inversely correlated with depression ($r = -.33$), anxiety ($r = -.22$), and hostility ($r = -.30$), and positively correlated with prosocial attitudes ($r = .26$) and confidence ($r = .23$) at T2. Community acceptance was inversely correlated with hostility ($r = -.16$) and positively correlated with prosocial attitudes ($r = .22$) at T2. Retention in school was only marginally correlated with higher levels of prosocial attitudes and behaviors ($r = .15$).

Predictors of Psychosocial Outcomes Over Time: Multiple Regression Analysis

Three potentially confounding variables were examined to determine whether they were associated with the variables of interest in this study: gender, age of child, and relative SES. Females in our sample were significantly more likely to experience rape ($p \leq .0001$). Our analyses also revealed that females had higher levels of hostility at T2 ($M = 22.67$, $SD = 4.67$) compared to males in the sample ($M = 19.47$, $SD = 6.16$, $t = 2.12$, $p \leq .05$). Females and males reported comparable levels of depression and anxiety symptoms as well as confidence. Age of participants was correlated with age of abduction (with older participants in the sample being abducted at older ages). Older youth had significantly lower levels of family acceptance ($r = -.28$, $p \leq .001$). Age was not significantly correlated with any other psychosocial outcomes investigated. Socioeconomic status was correlated with higher community acceptance at T2 ($r = .19$, $p \leq .05$). Higher SES was also correlated with higher average levels of prosocial attitudes ($r = .22$, $p \leq .01$) and confidence ($r = .25$, $p \leq .01$). Therefore, gender, age, and SES were entered as covariates in all regression analyses.

War-related violence and mental health adjustment. Table 4 displays regression analyses exploring levels of depression, anxiety, hostility, prosocial attitudes, and confidence at follow-up (T2). Adjusting for demographic variables and T1 scores, youth abducted into the fighting forces when they were younger ($\beta = -0.41$, $p \leq .05$) were likely to report more symptoms of depression at T2. In examining the effects of stress accumulation, we observed that witnessing general violence, experiencing rape, and having killed others during the war were not predictive of depression symptoms at T2, adjusting for all covariates.

None of the demographic variables investigated had an effect on anxiety level at T2. Witnessing general war-related violence was not a significant predictor of anxiety at follow-up while being involved in wounding or killing others was only marginally significant in predicting symptoms of anxiety ($\beta = 1.58$, $p \leq .10$). Of all risk factors studied, surviving a rape was the strongest predictor of anxiety at T2 controlling for anxiety levels at T1 ($\beta = 4.06$, $p \leq .05$) and adjusting for all other covariates. A history of having survived a rape contributed to an anxiety score more than half a standard deviation greater at follow-up.

In terms of hostility, surviving a rape predicted significantly higher levels of hostility at T2 ($\beta = 7.42$, $p \leq .001$) such that surviving a rape contributed to a hostility score a full standard deviation greater at follow-up upon adjusting for all other factors. A history of wounding or killing others ($\beta = 3.06$, $p \leq .05$) was also associated with hostility scores nearly a half standard deviation higher than the sample mean at follow-up. These patterns were consistent when the protective factors were added to the model in Step 3. Length of time with armed groups and age of abduction were not significantly associated with levels of hostility at follow-up (T2).

For adaptive outcomes, our analysis revealed that gender and SES were both strong predictors of prosocial attitudes and confidence levels at follow-up. In particular, females had significantly lower prosocial attitudes ($\beta = -3.13$, $p \leq .01$) and confidence ($\beta = -2.85$, $p \leq .05$) at T2, whereas living in wealthier families was associated with increased levels of prosocial attitudes ($\beta = 0.26$, $p \leq .05$) and confidence ($\beta = 0.34$, $p \leq .01$). Neither general witnessing of violence nor a past history of wounding or killing others played a significant role in predicting levels of confidence or prosocial attitudes. However, survivors of rape demonstrated higher levels of both prosocial behaviors ($\beta = 5.22$, $p \leq .001$) and confidence at follow-up ($\beta = 3.40$, $p \leq .05$).

Individual, family, and community factors and psychosocial adjustment. Among the protective factors examined, staying in school and changes in community acceptance exerted the largest positive impact on psychosocial adjustment, indicating their importance for facilitating stress adjustment in this setting. In particular, increases in community acceptance between T1 and T2 (adjusting for baseline community acceptance) were significantly associated with lower depression ($\beta = -0.35$,

Note. $N = 156$. For each predictor, we report parameter estimate, associated p value and 95% confidence intervals. R^2 = percentage of outcome variance explained by each regression model; ΔR^2 = difference in percentage of outcome variance explained between regression models; SES = socioeconomic status.

$^{\dagger}p \leq 0$. $^{*}p \leq .05$. $^{**}p \leq .01$. $^{***}p \leq .001$.

$p \leq .05$), increased prosocial attitudes and behaviors ($\beta = 0.62$, $p \leq .001$), and increased confidence ($\beta = 0.32$, $p \leq .05$) at T2. Staying in school between T1 and T2 was predictive of greater prosocial attitudes at follow-up ($\beta = 1.55$, $p \leq .05$). Although it did not reach the $p \leq .05$ level of significance, perhaps in part due to 77% of subjects giving the highest possible rating on this scale, increased family acceptance demonstrated an inverse relation with hostility ($\beta = -2.17$, $p \leq .10$). None of the other protective covariates appeared to exert a positive effect on anxiety. None of the conceptual groups of interaction terms were found to significantly improve the fit of these final main effects models as assessed by joint *F* tests.

Discussion

In this analysis, we obtained partial support for both a risk accumulation and a stress adjustment model of psychosocial well-being among former child soldiers. We tested the association between exposure to war-related experiences of violence and psychosocial adjustment over a 2-year period of follow-up. In addition, we were interested in the role of protective factors at the individual, family, and community levels in terms of their relation with improved adjustment. Finally, we explored the potential mitigating impact of significant individual, family, and community protective factors in the relation between war experiences and psychosocial adjustment. Although average levels of depression, anxiety, and hostility remained stable between baseline and follow-up, important changes were observed among a number of subgroups in the sample.

War-Related Experiences and Mental Health Adjustment

Although most children who survive wars are exposed to some degree of violence, our analyses indicated that two forms of violence common among former child soldiers—wounding or killing others and rape—had a particularly toxic influence on long-term psychosocial adjustment, particularly with regard to the outcomes of hostility and anxiety. These two categories of war traumas are set apart from the widespread witnessing of violence commonly reported among war-affected youth (Barenbaum et al., 2004; Lustig et al., 2004) by their intimate nature and intensity. However, research on child soldiers to date has not examined the specific longitudinal influence of these more severe forms of violence exposure.

Standard approaches to the measurement of war-related violence typically add all war-related experiences into a single total exposure score. Such an approach may mask important dynamics related to the most severe forms of violence exposure, particularly those that distinguish the experiences of former child soldiers (Hatch & Dohrenwend, 2007; Hundt, Chatty, Thabet, & Abuateya, 2004; Netland, 2005). Our work builds on the work of Macksoud and Aber (1996) who developed the CWTQ to address the need to make qualitative distinctions between different types of war-related experiences faced by children and youth. Given the widespread trauma, violence, and loss that characterize most war-affected young people, it is important to distinguish between forms of violence that are frightening—but widespread—and those that are less common—but distinctly toxic—in order to accurately identify those at risk for poor adjustment over time. It is important to note that witnessing of general war violence, although very common in this sample, was not a strong predictor of psychosocial adjustment over time. In contrast, the effects of experiencing rape and wounding or killing others were longlasting.

Of all the psychosocial outcomes investigated, the significant increases in hostility observed among youth who reported rape or wounding or killing are particularly concerning in that these exposures are much more likely to accumulate in child soldiers. Participation in wounding or killing others was a significant predictor of hostility and remained a marginal predictor of anxiety even upon adjusting for all other variables examined in these analyses. The relations we observed between extreme war experiences and these mental health problems are consistent with observations made in other studies of former child soldiers (Annan et al., 2006; Santacruz & Arana, 2002) as well studies of adult war veterans (Hofmann, Litz, & Weathers, 2003; Maguen et al., 2006) and adult combatants in neighboring Liberia (Johnson et al., 2008).

Although the present analysis was limited by a small sample of females, gender was an important predictor of decreased prosocial attitudes and lower confidence over time. This finding likely indicates the ''double indemnity'' facing female former child soldiers in this context who were not only involved in violence perpetration but also frequently face greater stigma upon return home. Our qualitative data have indicated that these young women face increased risk of community stigma due to perceptions that they have been made impure or promiscuous by sexual violation (Betancourt, Simmons, et al., 2008).

The finding in our data of an association between surviving a rape and increased confidence and prosocial attitudes was unexpected but must be considered in light of the dynamics of the Sierra Leone conflict. It is important to note that, on average, the youth in our sample had spent more than 5 years with the RUF. The RUF were well known for their brutality and harsh techniques of indoctrination and suppression, particularly in their treatment of child soldiers. Given this context, any former child soldier who made it through the war alive likely developed and relied upon a number of survival strategies to navigate such a harsh and dangerous environment. Some of these young people, particularly those who survived abuse, may actually possess a sense of resourcefulness that is exhibited in improved confidence and sense of agency over time. Indeed, many of the items measured in the confidence subscale capture such dynamics (e.g., feeling calm under pressure, confident in doing things on one's own).

In our qualitative data, prosocial behaviors, particularly the efforts of former child soldiers to be kind to others and have positive interactions, were described as a means of signaling to others that a young person was not a threat or morally corrupt. As a female former child soldier explained: "My parents accepted me … but other people in the community [did] not understand. … I later mingled with them [after that they] have observed that I am not a bad person. … I was very kind to everybody and we started to do things in common."

Our finding of a significant relation between a younger age of abduction and increased levels of depression over time aligns with recent developmental science indicating that exposure to toxic stress may be most damaging during sensitive periods in a child's development (National Scientific Council on the Developing Child, 2005; Shonkoff & Phillips, 2000). In addition, the lack of association between length of time with the fighting forces and any of the psychosocial outcomes (adjusted for severe violence exposures) indicates that severe violence exposures, rather than absolute length of abduction, are most important for predicting psychosocial adjustment over time.

Protective Factors and Mental Health Adjustment

Just as the presence of distinct toxic exposures must be considered in identifying which war-affected youth are most at risk for poor psychosocial adjustment, the presence of certain protective processes must also be evaluated. Consistent with research on the psychosocial benefits of school participation for children affected by armed conflict (Betancourt, 2005; Elbedour, Bensel, & Bastien, 1993; Loughry et al., 2006; Sommers, 2003), we found that staying in school was associated with improved prosocial attitudes and behaviors. In the Sierra Leonean context, failure to find a greater protective effect of school retention on negative mental health outcomes such as anxiety, depression, and hostility may be due to poor-quality schools and the limited availability of psychosocial supports in the present education system. Despite the fact that Sierra Leone's secondary schools serve a cohort of youth whose lives were deeply affected by the war, very few secondary schools offer teacher salaries that lead to quality teaching, let alone time, training, or staff to provide support and guidance for traumatized children (Betancourt, Simmons, et al., 2008).

The Mitigating Effect of Community Acceptance

Overall, community acceptance emerged from our analysis as an important predictor of reduced depression over time as well as improvements in prosocial attitudes and confidence. These findings are consistent with other research pointing to community acceptance as an important factor in understanding the long-term reintegration of former child soldiers (Allen & Schomerus, 2006; Boyden & de Berry, 2004; Bracken & Petty, 1998). Importantly, the influence of community acceptance was found to have a protective effect (Luthar, Cicchetti, & Becker, 2000) on depression and an enhancing effect on confidence and prosocial attitudes of former child soldiers regardless of whether they had a history of the most severe violence exposures. This finding speaks to the importance of postconflict efforts to sensitize communities and encourage community acceptance of former child soldiers. In return, it appears that when former child soldiers experience improvements in community acceptance, they may return the gesture with increased positive effort (i.e., helping others, sharing, initiating activities). This finding speaks further to the agency of war-affected youth who, despite exposure to some of the most horrendous experiences of war, may make an extra effort to be helpful and kind to others when the larger community projects a willingness to accept them.

Overall, our study identified only a few protective factors that might assist the recovery of former child soldiers who have experienced the most severe and cumulative forms of war trauma. In fact, the magnitude of the effects of war-related stressors, particularly surviving rape and being involved in wounding or killing, were much larger than those associated with protective factors such as staying in school and experiencing improvements in community acceptance. Our finding that the stress-adjustment effects in this sample are generally weaker than the stress-accumulation effects has important public health implications. It suggests that we have a long way to go before being able to fully mitigate the effects of particularly toxic stressors in the lives of war-affected youth, such as rape and involvement in wounding or killing others.

In future research, the search for additional sources of protection must be broadened to consider other forms of protection and support. It also remains important to evaluate the influence of access to traditional healing resources as well as more formal clinical interventions in this population. Despite the severe stressors characterizing some former child soldiers, it is important to note that there has yet to be a rigorous evaluation of interventions addressing the influence of such traumatic events (or postconflict aftereffects such as stigma) on child mental health and development.

Overall, our findings indicate no justification for an approach to targeting services at war-affected youth based on simple labels such as *former child soldiers* without individualized assessment. Although wounding or killing others and surviving rape were important risk factors in our sample, these exposures did not characterize the majority of the sample. However, for youth with accumulated exposures to the most toxic forms of violence, access to rehabilitative services, such as clinical mental health treatment or other traditional approaches to healing, may be some of the few pathways forward.

Further longitudinal research is necessary to truly disentangle the processes involved in the psychosocial adjustment of former child soldiers, the effects of extreme war exposures, and their relation to protective processes over time. In future research, more information is needed about the functions of family and peer relations as resources and supports, as well as potential sources of continued strain in the process of reintegration. Beyond retention in school, the degree to which former child soldiers have been involved in other skills training programs, income-generating activities, and the degree to which they have access to other mentors or positive peers must be examined.

Limitations

There are a number of study limitations must be noted. First of all, an inherent challenge within cross-cultural research is studying constructs in non-Western settings, where local notions of family or community acceptance are likely to be shaped by local context (Canino & Alegria, 2008; Honwana, 2006; Matias-Carrelo et al., 2003). To ensure cultural relevance, we addressed these challenges through gathering additional qualitative data about the constructs of interest as well as consulting local staff members and others working with war-affected youth. Although many of the constructs we studied, such as family and community acceptance, have particular relevance to Sierra Leone, to a large degree these constructs mirror mainstream theory about indicators of acceptance that have been used in prior research on the reintegration of adult soldiers following conflicts such as Vietnam (King, King, Fairbank, Keane, & Adams, 1998).

Further, the sensitive nature of the data collected may be affected by response bias, particularly for difficult events such as rape and perpetration of wounding or killing. Previous research with survivors of violence has suggested that errors in reporting violent experiences, particularly in underreporting, may derive from deliberate strategies on the part of study participants to keep violent events secret in an effort to avoid retribution, future harm, or stigma (Guterman & Cameron, 1997; Guterman, Cameron, & Staller, 2000). It is possible that this is the case in our sample, especially for the reporting of rape and perpetration, which would likely result in underestimations of the relations examined in this study.

In addition, age of the child and the time between the violent event and the time of reporting are also important factors to consider (Brandt, Ward, Dawes, & Flisher, 2005; Guterman et al., 2000; Tajima, Herrenkohi, Huang, & Whitney, 2004). In general, younger children (preschool age) tend to have a harder time accurately reporting violent events that may have happened to them (Tajima et al., 2004). However, in our data, these concerns are reduced somewhat by the fact that the respondents were adolescents reporting on experiences with violence only 2 years after the end of the war; thus, their reporting bias may be more akin to adult responses in similar situations.

The lack of baseline data on prewar mental health problems among youth in Sierra Leone limits our ability to compare the indicators of psychosocial adjustment observed in this sample to the general population. In addition, the challenge of identifying and retaining an appropriate comparison group remains one of the most persistent challenges in conducting research of this nature. Due to the dynamics of the war, it is impossible to identify a group of youth comparable with this cohort who did not experience some degree of exposure to war-related violence. Although our study design initially included a comparison group, the loss to follow-up in this group between T1 and T2 was too great to allow for reliable comparisons, a challenge that we intend to remediate in future stages of this research.

Finally, because our sample represents a cohort of youth demobilized over a specified time period rather than a regionally representative sample, our findings are limited in their ability to be generalized nationally. However, because our sample draws from more than four districts in Sierra Leone, we have no reason to believe that findings from this sample are not reflective of dynamics observed in other parts of the country.

Implications

It is important to consider the findings presented here in light of the current situation of social and mental health services for war-affected youth in Sierra Leone. At present, policy makers in Sierra Leone and the international community are focused on economic development and stability for the country. However, failure to address the consequences of the war on Sierra Leone's young generation threatens the development of human capital and the investments being made in education and youth employment schemes (Mac-Ikemenjima, 2008). Our finding of a progressive deterioration over time in the adjustment of the most highly traumatized former child soldiers, contributing to increased levels of hostility for those who had killed, and increased anxiety and hostility among rape survivors, is of particular concern. Although rape survivors demonstrate more complexity in their response to war (not only manifest in greater risk for mental distress but also a capacity for improved confidence and prosocial attitudes), those with a history of wounding or killing others show only negative outcomes with time. In Sierra Leone, it is important to note that a number of programs have evolved to attend to the consequences of rape and other forms of gender-based violence; however, very little attention has been given to addressing the mental health consequences of perpetrating atrocities. Certainly, research from other wars has indicated that such experiences have profound developmental consequences and pose persistent risks for mental health problems (Davison et al., 2006; Grossman, 1996; King & King, 1999).

Without more targeted attention to support these young people to make the best of the opportunities available to them in development efforts, the risks facing this particularly vulnerable cohort are likely to become more intractable. Such lost opportunity will have personal consequences for the youth in question, a compelling enough reason to act on human rights grounds alone. However, failure to truly address such long-term challenges to true reintegration and *rehabilitation* could very well have broader sociopolitical and security consequences for the society and country at large.

Unfortunately, many DDR programs operating internationally are hampered by inadequate funds to address the social services needs of war-affected youth and families over the long term. The funding streams, technical assistance, and human resources developed during the initial humanitarian emergency and DDR period have not translated into sustainable systems of care. Although significant efforts were made in Sierra Leone's DDR efforts to provide assistance to former child soldiers in the immediate postconflict period, very few social or mental health services for war-affected youth of any kind remain today. With good reason, recent policy efforts have been cautious to rely on labeling or the targeting of only certain groups (such as former child soldiers) for services. However, in the attempt to avoid a focus on psychopathology or the singling out of specific groups for care in isolation of others, the reality of the residual trauma that some of these youth face has been minimized. As our data indicate, despite the dangers of labeling, there is an alarming concentration of particularly toxic risk factors among a portion of former child soldiers. Failing to ensure long-term monitoring, assessment, and follow-up of these particularly high-risk groups avoids the issue.

In conclusion, the present study contributes to the scant literature on the experiences of child soldiers globally by providing the first prospective longitudinal data on a cohort of males and females. It is our hope that this and future research can enhance our scientific understanding of the processes linking war-related traumas to psychological functioning and raise awareness among local governments and the international community of the importance of investing in reasonable, effective, and sustainable responses to support the mental health needs of *all* war-affected children.

University Medical Center of Hamburg

The present research examines posttraumatic resilience in extremely exposed children and adolescents based on interviews with 330 former Ugandan child soldiers (age = 11–17, female = 48.5%). Despite severe trauma exposure, 27.6% showed posttraumatic resilience as indicated by the absence of posttraumatic stress disorder, depression, and clinically significant behavioral and emotional problems. Among these former child soldiers, posttraumatic resilience was associated with lower exposure to domestic violence, lower guilt cognitions, less motivation to seek revenge, better socioeconomic situation in the family, and more perceived spiritual support. Among the youth with significant psychopathology, many of them had symptoms extending beyond the criteria for posttraumatic stress disorder, in keeping with the emerging concept of developmental trauma disorder. Implications for future research, intervention, and policy are discussed.

> *I want to get married, buy a bicycle, and put up a building.* (13-year-old boy, former child soldier)
>
> *I want to get a sewing machine so that I keep on making clothes and sell them to get some money.* (15-year-old girl, former child soldier)
>
> *I will be a person who is responsible in the community; I will be an honest person; I will be a person who helps people.* (16-year-old boy, former child soldier)

Note. Quotations stem from the interviews of the present study.

Millions of children around the globe suffer the consequences of armed conflicts. One of the most complex and severely traumatized group of war-affected children are child soldiers. Despite international bans, more than 250,000 children and adolescents are exploited as soldiers worldwide, almost half of them in Africa (Office of the Special Representative of the Secretary-General for Children and Armed Conflict, 2006). The term *child soldier* refers to any person under 18 years of age associated with an armed force or armed group in any capacity ranging from combatants to cooks (United Nations Children's Fund [UNICEF], 2007). During their time as soldiers, these youth are brutalized and cruelly abused by armed groups, and often forced to commit atrocities themselves. The literature on the psychological consequences of child soldiers' experiences is only now emerging and consists mainly of interview-based, ethnographic case studies (Betancourt et al., 2008). The ideological commitment of child soldiers (Kanagaratnam, Raundalen, & Asbjornsen, 2005), the situation of girl soldiers (McKay, Robinson, Gonsalves, & Worthen, 2006), the reintegration and psychological rehabilitation (Betancourt et al., 2008; Medeiros, 2007), and mental health status of former child

---

First and foremost, our gratitude goes to the children at Laroo Boarding School who made this research possible. We extend our gratitude to Malisa Mukanga and Rahel Duresso for their assistance with data collection, to Christophe Bayer for his creative ideas, and to Claus Barkmann, Monica Blotevogel, Tom Toepfer, Elizabeth Stephens, Bill Charette, Victoria Olsen, Monika Bullinger, and Georg Romer for their helpful comments on earlier drafts. This study was funded by the Children for Tomorrow Foundation.

soldiers (Bayer, Klasen, & Adam, 2007; Derluyn, Broekaert, Schuyten, & De Temmerman, 2004; Kohrt et al., 2008) have been investigated.

One of the most impressive phenomena of child development is the ability of many children to develop into healthy, well-adapted adults despite adversity and trauma. The current research addresses this underresearched phenomenon of positive adaptation following exposure to extremely adverse conditions of armed conflict and domestic violence.

Traumatic Experiences in Children and Adolescents

Many experiences of children in armed conflict can be classified as traumatic. A stressor is defined as traumatic when it threatens an individual's life or physical integrity and elicits a subjective response of fear and helplessness (American Psychiatric Association, 2000). This definition includes both objective characteristics of the event and subjective responses on the victim's side. Terr (1991) proposed a framework for childhood trauma that distinguishes between single-incident trauma (Type I) and repeated or prolonged trauma (Type II). These Type II traumas have been also termed *complex trauma* (Herman, 1992; van der Kolk, 2005) and describe the ''experience of multiple, chronic and prolonged, developmentally adverse traumatic events, most often of an interpersonal nature (e.g., sexual or physical abuse, torture) and early-life onset'' (van der Kolk, 2005), which are characteristic of the experiences of child soldiers.

Such experiences have detrimental effects on children's development. When exposed to unpredictable and uncontrollable danger, a child will immediately react to frightening stimulus with fight, flight, or freeze response without being able to learn from the experience. Resources normally dedicated to growth and development are allocated to survival instead (van der Kolk, 2007). This means they may not be able to complete developmental tasks, for example, the development of secure attachment relationships, of a stable and integrated self-concept, and of the competence to self-regulate emotion and behavior (van der Kolk, 2005).

Multiple Posttraumatic Outcomes in Children and Adolescents

Psychopathological Outcome

Children exposed to traumatic events are at risk of developing psychopathological symptoms (Pynoos, Steinberg, & Wraith, 1995; Yule, 2002). Terr (1991) described four characteristics related to childhood trauma that appear to last for long periods of time, regardless of the diagnosis. These are: repeatedly intrusive memories of the traumatic event, repetitive behaviors, trauma-specific fears, and altered attitudes toward people, life, and the future. The introduction of a new psychiatric disorder termed *posttraumatic stress disorder* (PTSD) in 1980 was an attempt to establish a diagnostic category to describe trauma reactions in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders*, 3rd Edition (*DSM–III*; American Psychiatric Association, 1980). The symptoms include repeated and unwanted reexperience of the event, hyperarousal, and avoidance of stimuli that could remind of the event. PTSD rapidly became the most frequently used outcome measure in the trauma literature.

Regarding prevalences of PTSD in former Ugandan child soldiers, two recent studies found that about one third (27%–34.9%) of Ugandan child soldiers developed the disorder according to *DSM–IV* criteria (Bayer et al., 2007; Okello, Onen, & Musisi, 2007). Other studies measured posttraumatic stress symptoms (PTSS) and indicated that almost all former Ugandan child soldiers (97%–98%) suffer from clinically significant PTSS (Amone-P'Olak, Garnefski, & Kraaij, 2007; Derluyn et al., 2004). These numbers seem much higher than the above reported prevalence rates on PTSD as they also include child soldiers with only moderate levels of symptoms. Even if not as thoroughly investigated as PTSD, other psychiatric sequelae are also common in war-affected children, particularly depression and anxiety disorders, dissociation, somatic complaints, as well as behavioral problems like aggressive and disruptive behavior (Qouta, Punamaki, Miller, & El-Sarraj, 2008; Shaw, 2003; Thabet, Abed, & Vostanis, 2004). Some studies on child soldiers concentrated solely on PTSD symptoms (Bayer et al., 2007; Derluyn et al., 2004), but recent research also indicates high prevalence rates for depression and anxiety (Kohrt et al., 2008; Okello et al., 2007).

When investigating war-traumatized children, two debates in the trauma literature are of crucial relevance. First, the diagnosis of PTSD might not integrate the full range of psychological sequelae following prolonged and repeated complex traumatic exposure (Herman, 1992), and second, the diagnosis of PTSD might not be developmentally sensitive (van der Kolk, 2005). Referring to both arguments, van der Kolk (2005) proposed the concept of developmental trauma disorder (DTD). This concept is close to what has been also described as *complex*

PTSD (Herman, 1992) or disorders of extreme stress not otherwise specified (DESNOS; Pelcovitz et al., 1997). Key features of DTD are emotional dysregulation, disturbed attachment patterns, behavioral reenactment (e.g., aggressive behavior), and persistently altered attributions and expectancies. Diagnostic criteria for DTD have been proposed by the Complex Trauma Task Force of the National Child Traumatic Stress Network (van der Kolk, 2007), but valid self-report measurements have yet to be developed. For assessing DTD, the Complex Trauma Task Force recommends a combination of PTSD measures and other measures of childhood psychopathology (e.g., Youth Self-Report [YSR]; Achenbach, Cook, Blaustein, Spinazzola, & van der Kolk, 2003). DTD has been proposed as new childhood trauma diagnosis for *DSM–V* (van der Kolk, 2005).

Resilient Outcome

Even in the face of severe adversity, some individuals show no signs of psychopathology. Already during the 1970s, the seminal work of Norman Garmezy, Michael Rutter, and Emmy Werner pointed out that a considerable proportion of children showed no pathology and high levels of competence, despite suffering risk experiences that would be expected to produce serious sequelae (Garmezy, Masten, & Tellegen, 1984; Rutter, 1987; Werner & Smith, 1982). This phenomenon is referred to as *resilience.*

There is an ongoing debate on whether resilience should be conceptualized as a personality trait or a mental health outcome (Luthar, Cicchetti, & Becker, 2000; Masten, 2007). Even when resilience is conceptualized in terms of outcome, conceptualizations vary in defining resilience as the absence of negative outcome, presence of positive outcome, or a combination of both. Recent approaches go even further and conceptualize resilience as a dynamic process when analyzing how risk and protective factors corroborate in modulating the impact of traumatic experiences on mental health outcome (Olsson, Bond, Burns, Vella-Brodrick, & Sawyer, 2003; Rutter, 1987).

In the face of highly adverse risk factors such as traumatic events, the absence of pathology is remarkable and may serve as the definition of resilience (Hoge, Austin, & Pollack, 2007; Vanderbilt-Adriance & Shaw, 2008). To date, only a few studies have been published examining resilience in trauma populations (Bonanno & Mancini, 2008). Instead, many studies on resilience investigated normative birth cohorts (Werner & Smith, 2001) or American middle-class samples (Criss, Pettit, Bates, Dodge, & Lapp, 2002). To understand resilience, however, it is also essential to focus on severely exposed samples, as resilience is not defined as a positive adjustment per se, but rather a positive adjustment in the context of high levels of adversity (Masten, 2001).

Due to heterogeneity in the operational definitions of adversity, adaptation, and resilience, the prevalence of resilience in high-risk samples is difficult to estimate. Vanderbilt-Adriance and Shaw (2008) concluded in their review that resilient outcomes above 25% are rare in higher risk samples (e.g., multiple risks, low socioeconomic status [SES]). In contrast, Bonanno, Galea, Bucciarelli, and Vlahov (2006) showed in a recent study that the prevalence of resilience in trauma survivors varied from 33% to 54% across different exposure categories.

Relating to these investigations, we emphasize the use of a relatively new term, *posttraumatic resilience*, to describe trauma survivors with a positive posttraumatic mental health outcome. A search of the PsychINFO database in June 2008 yielded 14,969 items referring to posttraumatic stress compared to only two items referring to posttraumatic resilience. In the absence of a definitive resilience research paradigm, Yehuda and Flory (2007) argued that investigators must clearly outline their definition of resilience. For the current research we defined posttraumatic resilience as the absence of clinically significant psychopathology in the aftermath of severe trauma exposure.

Risk and Protective Factors for Posttraumatic Mental Health Outcome

Masten, Cutuli, Herbers, and Reed (2009) distinguish between risk factors, promotive factors, and protective factors. A *risk factor* is defined as a measurable characteristic of a group of individuals or their situation that predicts negative outcome on a specific outcome criterion. *Promotive factors* and *protective factors* are defined as measurable characteristics of a group of individuals or their situation that predict positive outcome with respect to a specific criterion. While the first applies to factors that predict positive outcome in similar ways across risk levels, the latter refers to factors that predict positive outcome specifically in the context of risk or adversity. Although the predictors analyzed in the present research may predict better outcome in general, they appear to be particularly important under conditions of higher risk or adversity. We therefore refer to them as protective factors. Factors may relate to diverse domains (e.g., biological, psychological, sociological) and different levels within a domain (e.g., cognitive processes, personality traits; Kazdin, Kraemer, Kessler, Kupfer, & Offord, 1997).

In addition to trauma severity, female gender, low SES, and previous trauma or other childhood adversity are risk factors for posttraumatic psychopathology in children and adults (Brewin, Andrews, & Valentine, 2000; Pfefferbaum, 1997). In the absence of a posttraumatic resilience paradigm, variables can be drawn from two sets of research findings in the search for additional predictors. The resilience literature yields dispositional and social protective factors predicting positive outcomes and the trauma literature adds responses to trauma that are risk factors, as well as social support variables as protective factors for psychopathological outcomes.

Dispositional factors. Resilience research has a long-standing tradition of investigating dispositional attributes of well-adjusted children in the face of adversity (see Masten et al., 2009, for a review). Among other attributes, internal locus of control, a sense of meaning, social problem-solving skills, and strong self-esteem often have been implicated as protective factors for resilience (Masten et al., 2009; Rutter, 1985; Taylor, Kemeny, Reed, Bower, & Gruenewald, 2000). The concept of *hardiness* integrates many of these characteristics. It describes individuals who are committed to finding meaningful purpose in life, believe that one can influence one's surroundings and the outcome of events, and trust that one can learn and grow from both positive and negative life experiences (Kobasa, Maddi, & Kahn, 1982). Hardiness is associated with posttraumatic adjustment (King, King, Fairbank, Keane, & Adams, 1998). Furthermore, a positive orientation toward the future, comprising optimism and goal orientation, also is associated with good psychological adjustment in the context of adversity (Masten et al., 2009). Optimism is defined as the global expectation that the future will bring good things (Peterson, 2000). These globally positive expectancies are considered a major determinant of whether people continue to pursue valued life goals against the backdrop of adversity.

Parents and relationships. The resilience literature also strongly implicates the protective influence of parents and other supportive relationships for resilience in children and youth (Luthar, 2006; Masten et al., 2009). In the context of exposure to severe adversity, children in close proximity to effective caregivers fare better and young people who lose their parents are more vulnerable to psychopathology. Positive relationships with parents and other adults appear to provide emotional security as well as many forms of direct assistance during severe adversity. As children grown older, relationships with friends and romantic partners increase in importance. One of the most devastating effects of adversity is the destruction or loss of the fundamental protections afforded by caring adults and friends, such as when parents are killed.

Responses to trauma and perceived social support factors. Cognitive trauma theorists have focused on cognitive risk factors to explain the development and maintenance of posttraumatic psychopathology in adults and children (Ehlers & Clark, 2000; Ehlers, Mayou, & Bryant, 2003). The experience of traumatic events often changes the victim's thoughts and beliefs. For example, trauma survivors frequently experience guilt and self-blame (Kubany, 1994; Kubany et al., 1996). This guilt cognition can be related to having survived while others did not. It may also arise from a lack of justification of certain behaviors enacted during traumatic situations (Kubany, 1994). Guilt has been identified in trauma survivors such as victims of rape, battered women, and combat veterans (Kubany, Abueg, Kilauano, Manke, & Kaplan, 1997). Trauma survivors may also become preoccupied with feeling of unfairness and injustice, which may provoke rumination focusing on revenge (Orth, Montada, & Maercker, 2006). These responses can act as a block to cognitive change and thus serve to maintain PTSD. Further, aspects of the peritraumatic psychological response, predominantly dissociations, have been shown to be risk factors for posttraumatic outcome in adults and children (Brewin et al., 2000; Cook et al., 2003; Diseth, 2005; Ozer, Best, Lipsey, & Weiss, 2003). Finally, *perceived social support* has been described as a crucial protective factor for posttraumatic outcome (Bonanno, Galea, Bucciarelli, & Vlahov, 2007; Ozer et al., 2003). Perceived social support refers to the belief that specific transactions such as helping behavior would be provided by others if needed (e.g., by parents, teachers, friends). In the aftermath of trauma, perceived social support seems to serve an important secondary prevention role (Ozer et al., 2003).

The Present Research

Since the late 1980s Northern Uganda has been ravaged by the rebel terror of the Lord's Resistance Army (LRA). Eighty percent (1.4 million) of the population lives in camps for internally displaced people, many have been killed or tortured, and an estimated 25,000 children and adolescents have been forcefully recruited into the rebel forces (Coalition to Stop the Use of Child Soldiers, 2008). An estimated 24% of them are girls (Pham, Vinck, & Stover, 2007). Peace talks between the Ugandan government and the LRA began in July 2006 in southern Sudan. In November 2006, when this research was carried out, the atmosphere was tense with both hope for peace and fear of another failure in attaining a truce. While the total number of remaining LRA fighters is unknown, up to 2,000 women and children are believed to still remain with the rebel fighters (Coalition to Stop the Use of Child Soldiers, 2008).

In this study, we address several gaps in the literature on child soldiers. There is very little empirical research on adaptation and resilience in child soldiers, particularly with a focus on multiple risk and protective factors. We distilled four clusters of risk and protective factors both from resilience and trauma literature that may explain posttraumatic outcome over and above trauma severity during abduction. First, additional trauma and life stressors have been shown to be significant risk factors for posttraumatic outcome (Brewin et al., 2000). We therefore assessed the most critical additional trauma and life stressors for our sample, namely the loss of parents and exposure to domestic and community violence. Second, we addressed dispositional factors, such as hardiness and optimism, that are presumed to promote posttraumatic resilience (Kobasa et al., 1982; Scheier & Carver, 1992). Third, according to the trauma literature and previous research on child soldiers, dissociation, guilt, and revenge are presumed to have an impact on posttraumatic outcome (Bayer et al., 2007; Diseth, 2005). Finally, in addition to the assessment of social support, a known protective factor in trauma populations (Ozer et al., 2003), we assessed perceived spiritual support during crisis. As resilient individuals may experience some form of transient stress reaction following trauma exposure, we investigated former child soldiers living in the safe environment of a boarding school, protected from rebel attacks and domestic and community violence for 4 months prior to data collection.

Hence, we had four hypotheses for this study. First, we expected that a considerable proportion of the investigated child soldiers would be resilient according to our operational definition of resilience based on their mental health status: (a) not meeting criteria for PTSD, (b) not meeting criteria for depression, or (c) scoring below the multicultural cutoff for behavioral and emotional problems. Second, we hypothesized that trauma severity during abduction would be a significant risk factor for posttraumatic outcome. Third, we hypothesized that loss of parents and domestic and community violence significantly would predict posttraumatic outcome. Finally, we hypothesized that person variables (dispositional variables, responses to trauma, perceived external support) would predict posttraumatic outcome over and above what can be predicted from trauma severity.

Method

Participants

The sample of this cross-sectional field study consisted of 330 former Ugandan child soldiers (48.5% girls). Children were on average 14.44 years old (*SD* = 1.57, range = 11–17 years). The children's ethnicity was mainly Acholi (61.5%) and Langi (38.2%), and they originated from the five war-torn northern districts of Uganda (Apac 18.2%, Gulu 21.8%, Kitgum 17.3%, Lira 20.6%, Pader 20.6%, Other 1.2%). Luo was the first language of all children. Ninety-eight percent of the children were Christians. Their fathers' occupations were mainly subsistence farmer (63.6%), trader (17.1%), or security and military servant (12.0%). Children had on average five biological siblings (range = 0–12).

Procedures

We recruited participants from a boarding primary school in Gulu Town in Northern Uganda, a special-needs school designed to support war-traumatized children, established by the government of Uganda. The only one of its kind in the entire country, the school aims to help war-traumatized children reach the same curriculum level as students in the public school system. Due to financial problems, no specialized interventions, like psychosocial programs, could be started at the school prior to our data collection. The selection of children for admission at the school required the assessment of traumatic war experiences and related symptoms with a questionnaire carried out by trained assessors, giving priority to extremely war-affected children. Community leaders confirmed war involvement of children during the selection process. Children were picked in almost equal proportions from the five war-torn northern districts of Uganda. The selection process required that 60% of the school population be female. The school opened in July 2006, meaning children had been in the safe environment of the boarding school, protected from rebel attacks and domestic and community violence for 4 months prior to data collection.

Written informed consent from the local authorities and oral informed consent from students and teachers were obtained for the study. Children were eligible if they had been a child soldier for at least 1 month, had returned from the armed group at least 6 months prior to the study, and were currently between 11 and 17 years of age. Children's abduction status was confirmed by teachers. Inclusion criteria were met by 358 students of the school. Three children declined to participate and were not asked to justify their decision. Children were assured that they were free to withdraw from the study at any point. None withdrew during data collection. Likert scales were explained and rehearsed in detail with all children. According to teachers' assessment, 45.9% of the children were illiterate. Questionnaires were read aloud to illiterate children by trained interviewers, while trained interviewers helped literate children fill out the questionnaires in class. The need for explanation and examples transformed the self-report method into an interview. Psychiatrists from Gulu Hospital were available to provide psychological support at all points of data collection, although support was never necessary. The school received books for a library as honoraria for supporting the assessment, while interviewers received payment. Data from 25 pupils could not be analyzed due to missing inclusion criteria or invalid data, resulting in a final population of 330 pupils for analysis.

The study was approved by the ethics committee of the Medical Association of Hamburg and by the Uganda National Council for Science and Technology.

Measures

Lacking well-validated concepts and measures based on research with Ugandan populations, we adapted concepts and measures from the trauma and resilience literature. The adaptability of these measurements was discussed with experienced mental health professionals and anthropologists originating from Uganda or who had done research in the country. All instruments were translated and back-translated into the local language (Luo) by linguists at the Institute of Languages at Makarere University in Kampala. The translators and the study director collectively resolved problems in the translated version by comparing the original English version with the back-translation. The administration of all materials was tested in a pilot phase for acceptance, adequacy, and applicability.

Sociodemographic Variables

We assessed age, gender, and SES of the participant's families. SES was operationalized by parents' educational levels and families' material resources. Items were taken from the Child War Trauma Questionnaire (CWTQ; Macksoud, 1992). Educational level of each parent was assessed by one item scored 0 (*can't read or write*), 1 (*has had some schooling*), 2 (*has completed primary school*), 3 (*has completed secondary school or vocational school*), or 4 (*holds a college degree*). Family material resources were assessed by four items pertaining to four categories of resource (i.e., food, shelter, clothing, and income) rated on scale from 0 (*very poor*) to 4 (*very rich*). These six items were added to a sum score. Higher scores indicate higher SES. The internal consistency for the current sample was Cronbach's alpha = .78. These simple measures of SES and educational level were discussed with experts in the field and seemed to have high face validity for the current sample.

Trauma Severity During Abduction

By definition, children who were abducted to serve as child soldiers experienced a traumatic event. To quantify trauma severity during abduction, we measured the reported number of traumatic events. We define both the experience of being a victim as well as that of being a perpetrator of violence as traumatic events, as children were forced to commit atrocities. Our Child Soldiers Trauma Questionnaire (CSTQ) is a 19-item yes–no statement questionnaire based on our own previous research on Ugandan child soldiers (Bayer et al., 2007) and the CWTQ (Macksoud, 1992). The CSTQ consisted of two subscales: The 13-item Victim Subscale (i.e., abduction; exposure: shooting, bomb explosion, massacre, air raid; deprivation: food, water; witness: injury, killing; victim: death threats, beatings, injury, rape) and the six-item Perpetrator Subscale (i.e., perpetrator: fighting, looting, abduction, torture, injury, killing). The internal consistency for each subscale was high (Cronbach's alpha = .73 for the Victim Subscale and Cronbach's alpha = .76 for the Perpetrator Subscale).

Posttraumatic Mental Health Outcome

To assess *PTSD* and *depression* we used the two accordant modules of the MINI-KID. The MINI-KID is the child and adolescent version of the Mini International Neuropsychiatry Interview (MINI; Sheehan et al., 1998), a short structured interview with axis 1 diagnostic categories of the *DSM–IV*. The MINI showed good reliability and validity coefficients compared to the Composite International Diagnostic Interview and to the Structured Clinical Interview for *DSM–IV* (Sheehan et al., 1998) and has recently been used for the first time in a study in Uganda (Okello et al., 2007). In addition to PTSD and depression we screened for a broad variety of *behavioral and emotional problems* using the YSR (Achenbach & Rescorla, 2001). The YSR is a widely used self-report instrument containing 105 problem items (e.g., ''I worry a lot,'' ''I destroy things belonging to others''). The scale consists of the following syndrome clusters: anxious-depressed, withdrawn-depressed, somatic complaints, social problems, thought problems, attention problems, rule-breaking behavior, and aggressive behavior. Items are rated 0 (*not true*), 1 (*somewhat or sometimes true*), and 2 (*very true or often true*) on the basis of the preceding months. All items summed up form a Total Problems score. The YSR has been shown to have excellent psychometric qualities (Achenbach & Rescorla, 2001). The YSR has been used in over 6,000 publications reporting findings from 65 countries (Achenbach & Rescorla, 2007). The multicultural application of the YSR is based on the vast amount of multicultural research and enables users to display problem scale scores in relation to sets of norms based on societies that were found to have relatively low scores (Group 1), medium scores (Group 2), or high scores (Group 3; Achenbach et al., 2008). Group 2 of the multicultural norms, which are also labeled *standard norms*, are recommended if norms for a certain population are missing (Rescorla et al., 2007). The only published African norms for the YSR are for Ethiopia, which are allocated to Group 2 (Mulatu, 1997). We used Group 2 norms based on the above arguments. Cronbach's alpha for the current sample was .95 for the Total Problems score.

Operationalization of Posttraumatic Resilience

As noted earlier, posttraumatic resilience was defined by the absence of psychopathology operationalized by (a) not meeting criteria for PTSD, (b) not meeting criteria for depression, and (c) scoring below the multicultural cutoff for behavioral and emotional problems (YSR).

Additional Trauma and Life Stressors

Loss of parents was assessed by asking whether parents were deceased. Thus, *loss of parents* was defined as losing mother, father, or both parents through death, no matter what the cause.

Exposure to *domestic and community violence* was assessed with a self-developed checklist based upon a recent report on violence against children in Uganda (Naker, 2005). This report refers to experiences and perspectives on violence against Ugandan children of 1,406 children and 1,093 adults based on a survey using complementary research methods (i.e., questionnaires, focus group discussions, narrative role plays, key informant interviews). Four main areas of violence against children were identified: physical, emotional, sexual, and economic. Our checklist contained 19 yes–no statements with 13 items pertaining to violence experienced at home (i.e., physical violence: caning, burning, locking up; emotional violence: shouting, insulting, threatening, ignoring; sexual violence: sexual insults, sexual touches, rape; economic violence: denying food, overworking, denying money for school fees and health care) and 6 items concerning violence experienced in the community including school (i.e., physical violence: caning, burning, locking up; sexual violence: sexual insults, sexual touches, rape). The internal consistency for the current sample was Cronbach's alpha = .82.

Dispositions

To assess *hardiness* we used the 10-item version of the Connor–Davidson Resilience Scale (CD–RISC; Connor & Davidson, 2003; Campbell-Sills & Stein, 2007). Items are rated on a 5-point Likert scale ranging from 0 (*not true at all*) to 4 (*true nearly all the time*), with higher scores reflecting greater abilities to tolerate experiences such as change, personal problems, illness, pressure, failure, and painful feelings (e.g., ''I am able to adapt when changes occur,'' ''I deal with whatever comes my way,'' ''I tend to bounce back after illness, injury, or other hardships''). The 10-item version displayed good psychometric properties and is highly correlated with the original 25-item version (r = .92; Campbell-Sills & Stein, 2007). Internal consistency for the current sample was Cronbach's alpha = .75.

To assess *positive future orientation* we used the Positive Future Orientation Subscale of the Adolescent Resilience Scale (ARS; Oshio, Kaneko, Nagamine, & Nakaya, 2003). It contains five items referring to optimism and goal orientation rated on a 5-point Likert scale (e.g., ''I feel positive about my future,'' ''I strive toward my future goals''). The subscale has been found reliable and valid in other studies (Oshio et al., 2003). Internal consistency for the current sample was alpha = .73.

Responses to Trauma

To assess *peritraumatic dissociation*, the Peritraumatic Dissociative Experiences Questionnaire was used (RAND PDEQ; Marshall, Orlando, Jaycox, Foy, & Belzberg, 2002). The eight-item instrument, rated on a scale ranging from 0 (*not at all true*) to 4 (*extremely true*), asks respondents to what extent they experienced depersonalization, derealization, and altered sensations at the time of the traumatic events (e.g., ''What was happening didn't seem real, like I was in a dream or watching a movie''). The RAND PDEQ has demonstrated good internal consistency and test–retest reliability, as well as discriminant and convergent construct validity in both community violence survivors and individuals who experienced sexual abuse (Marshall et al., 2002). The internal consistency for the current sample was Cronbach's alpha = .82.

To assess cognitive aspects of *guilt* we used the 22-item Guilt Cognitions Scale of the Trauma-related Guilt Inventory (TRGI; Kubany et al., 1996). Items are scored on a 5-point scale ranging from 0 (*never* or *not at all true*) to 4 (*always* or *extremely true*; e.g., ''I blame myself for what happened''). The TRGI has high internal consistency and adequate temporal stability (Kubany et al., 1996). TRGI scales were significantly correlated with other measures of guilt in validity studies with Vietnam veterans and battered women (Kubany et al., 1996). The internal consistency for the current sample was Cronbach's alpha = .78 for the Guilt Cognitions Scale.

Participants' motivation to seek *revenge* against transgressors was measured by the Revenge Motivations Subscale of the Transgression-Related Interpersonal Motivations Scale (TRIM; McCullough et al., 1998). The revenge subscale comprises five items that measure motivation to seek revenge (e.g., ''I'll make him or her pay back''). Higher scores indicate higher revenge. The subscale has a high internal consistency ($\alpha = .90$; McCullough et al., 1998) and evidence of construct validity (McCullough, Bellah, Kilpatrick, & Johnson, 2001; McCullough et al., 1998). The internal consistency for the current sample was Cronbach's alpha = .81.

Perceived External Support

Perceived social support during stressful situations was measured by the item ''I have at least one close and secure relationship which helps me when I am stressed.'' The item was rated on a 4-point scale, higher scores indicating higher support. We assessed *perceived spiritual support* by asking children to respond to the following item ''During stressful situations I wonder whether God has abandoned me.'' This item was taken from a measure of spiritual coping (RCOPE; Pargament, Smith, Koenig, & Perez, 1998). The item was rated on a 4-point scale and reverse coded. Hence, higher scores indicate higher perceived spiritual support.

Results

Descriptive Statistics

Experiences During Abduction

On average, children were abducted at 10.75 years of age (*SD* = 2.30, range = 5–16 years). All children in the sample were abducted by rebel attacks, one exception being a child born in captivity. Different tasks were assigned to children during their captivity: 41.8% were assigned primarily front-line tasks, for example, fighting, looting, abducting civilians (55% for boys and 26.8% for girls); 28% performed mainly logistic tasks, for example, carrying loads, spying, escorting commanders (34.3% for boys and 20.8% for girls); and 27.7% were assigned domestic chores, for example, cooking, caring for younger children (10.1% for boys and 47.7% for girls). The children experienced several traumatic events. For example, 90.6% of the children were beaten by armed forces, 87.9% witnessed murder, 86.4% were threatened with death, and 25.8% were raped by members of the armed group (22.4% for boys and 29.4% for girls). The average score on the Victim Subscale of CSTQ was 10.26 (*SD* = 2.30, range = 1–13). Many children were forced to commit atrocities. For example, 65.2% looted houses, 59.1% abducted other children, and 52.6% killed another person. The average score on the Perpetrator Subscale of CSTQ was 3.36 (*SD* = 2.00, range = 0–6).

The average time spent in abduction was 19.81 months (*SD* = 17.72, range = 1–108) and children had returned from the armed group 31.75 months prior to data collection (*SD* = 17.86, range = 6–105). Under the risk of capture and death, 81.2% of the children had escaped the rebel forces. More than one third (38.6%) of the children had been abducted more than once, in some cases up to five times.

Additional Trauma and Life Stressors

Before entering the boarding school, 97.2% of the children had lived with family members or relatives. Many children had lost one or both parent(s): 43.1% were double orphans and 36.7% were single orphans. Children reported frequent experiences of domestic and community violence (88.8%). On a scale of 19 experiences, children reported on average 5.43 violent acts (*SD* = 4.03, range = 0–19).

Posttraumatic Outcome

More than every fourth child (27.6%) showed a resilient mental health outcome. Thus, 72.4% showed significant symptoms of psychopathology at outcome, including 33% who met *DSM–IV* criteria for PTSD and 36.4% who met criteria for major depression (18.5% qualified for diagnoses of both disorders). Compared to multicultural norms, 61.2% of the children scored above the cutoff for behavioral and emotional problems. No significant gender differences regarding mental health outcomes were found, PTSD: $\chi^2(1, N = 330) = 0.04$, $p = .84$; depression: $\chi^2(1, N = 330) = 0.17$, $p = .73$; and behavioral and emotional problems: $t(328) = .11$, $p = .91$. We split the sample in two age groups: younger adolescents (11–13 years, $n = 92$) and older adolescents (14–17 years, $n = 234$). Younger adolescents displayed significantly lower rates of PTSD and depression than older adolescents, PTSD: 23.9% versus 36.8%, $\chi^2(1, N = 330) = 4.91$, $p = .027$; depression: 27.2% versus 39.3%, $\chi^2(1, N = 330) = 4.23$, $p = .04$.

Mean values and standard deviations of psychological predictors of posttraumatic outcome are presented in Table 1. Table 2 displays zero-order correlation among all key variables. To control for possible conceptual overlap between responses to trauma and posttraumatic outcome in this study, the guilt items were removed from the outcome scales. Correlations were virtually as strong as with the full scales, indicating that the correlation was not a methodological artifact.

Multivariate Analysis Predicting Posttraumatic Resilient Outcome

Risk and Protective Factors

Hierarchical multiple logistic regression analysis was used to test the association of risk and protective factors with posttraumatic status. The rationale for entry order was as follows: In Step 1, we tested the association of sociodemographic variables with posttraumatic outcome and controlled these variables for further analysis steps. In Steps 2 and 3, we tested the hypothesized association of trauma severity during abduction and additional trauma and life stressors with posttraumatic outcome. In Step 4, we tested whether person variables predict posttraumatic outcome over and above what can be predicted on the basis of sociodemographic variables and trauma severity.

$^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

The regression model controlled length of time since returning from abduction.

Hence, in Step 1, gender, current age, family SES, age at abduction, and length of abduction were entered into the regression equation. These variables accounted for 10% of the variance, Nagelkerke $R^2 = .10$, $\chi^2(5, N = 330) = 13.94$, $p = .016$. In Step 2, we added trauma severity during abduction (i.e., number of traumatic events victim, traumatic events as perpetrator), which did not significantly improve the prediction of outcome, $R^2_{\text{change}} = .01$, $\chi^2_{\text{change}}(2, N = 330) = 2.36$, $p = .31$; $R^2 = .11$, $\chi^2(7, N = 330) = 16.30$, $p = .02$. In Step 3, we entered additional trauma and life stressors into the regression equation (i.e., loss of parents, domestic and community violence). The accuracy of prediction increased significantly to 24% variance explained, $R^2_{\text{change}} = .13$, $\chi^2_{\text{change}}(2, N = 330) = 20.37$, $p < .001$; $R^2 = .24$, $\chi^2(9, N = 330) = 36.67$, $p < .001$. In Step 4, we entered the person variables into the regression function: dispositional factors (i.e., hardiness, positive future orientation), responses to trauma (i.e., dissociation, guilt, revenge), and perceived external support (i.e., social, spiritual support). Step 4 resulted in a significant increase in explained variance to 43%, $R^2_{\text{change}} = .19$, $\chi^2_{\text{change}}(7, N = 330) = 34.18$, $p < .001$; $R^2 = .43$, $\chi^2(16, N = 330) = 70.86$, $p < .001$.

Most Critical Predictors

Searching for the most critical predictors, six variables of the regression model proved to be significant predictors of posttraumatic resilience. Controlling for all other variables, higher age was a risk factor (OR = 0.72) and high family SES was a protective factor (OR = 1.11). Domestic and community violence was a risk factor (OR = 0.81) as were strong guilt cognitions and revenge motivation (guilt: OR = 0.96; revenge: OR = 0.92). Finally, children's perceived spiritual support was a protective factor and almost doubled the odds of resilience as defined in this study (OR = 1.91). Regression coefficients of all predictors are displayed in Table 3.

Interaction Effects

A second hierarchical multiple logistic regression analysis was used to test for the interaction effect between gender and age, the interaction effect between trauma severity and age, as well as the interaction effects between trauma severity and each of the most important hypothesized protective factors (i.e., hardiness, positive future orientation, perceived social support, and perceived spiritual support) in the prediction of posttraumatic mental health outcome. To compute these analyses, we

Perceived spiritual support	**.65**	**.17**	**14.22**	**.00**	**1.91**	**1.37–2.68**

Note. Model fit: $\chi^2(16, N = 330) = 70.86$, $p < .001$, Nagelkerke $R^2 = 43.2\%$. Controlled for time since return. Significant predictors ($p < .05$) indicated in boldface. SES = socioeconomic status.

composed an overall trauma severity measure of trauma during abduction, loss of parents, and domestic and community violence (Cronbach's alpha = .85). All continuous variables were centered prior to forming interaction terms. After controlling for main effects, we tested for interaction effects: first, the interaction of gender and age; second, of trauma severity and age; and third, of trauma severity and the four protective factors respectively, predicting posttraumatic outcome. None of the interaction terms was significantly associated with posttraumatic outcome.

Discussion

Child soldiers are one of the most severely traumatized populations of children and adolescents. Despite the extremely high level of adversity exposure, close to 30% of children showed a posttraumatic resilient outcome according to our operational definition. The prevalence rate of PTSD found in the presented study is consistent with other recent studies on child soldiers (Bayer et al., 2007; Okello et al., 2007). In addition to PTSD, results indicated high rates of depression and emotional and behavioral problems in these former child soldiers. These results, in line with growing evidence in the trauma literature, suggest that the concept of PTSD does not fully capture the reaction to repeated and prolonged interpersonal trauma of child soldiers and may be better described by concepts such as developmental trauma disorder (van der Kolk, 2005). Consideration of risk and protective factors added substantially to the prediction of posttraumatic status among these child soldiers, over and above sociodemographic variables and trauma severity during abduction. These findings show convergence and divergence with findings on resilience in Western populations.

Demographic and Trauma Variables

When controlling for all other variables, gender did not relate to resilience. This finding applied to all mental health outcome measures, that is, PTSD, depression, and behavioral and emotional problems. In contrast, most epidemiological studies in Western population samples indicate female gender as a risk factor for pathology in adolescents whether the samples were traumatized (Breslau & Anthony, 2007; Giaconia et al., 1995) or nontraumatized (Rescorla et al., 2007; Twenge & Nolen-Hoeksema, 2002). There is ongoing controversy on whether these gender differences are due to gender-based response tendencies, intrinsic vulnerability among females, or whether it might be explained by gender differences in type and extent of trauma exposure, especially referring to sexual trauma (Breslau, Chilcoat, Kessler, Peterson, & Lucia, 1999; Cortina & Kubiak, 2006).

Older children showed more mental health problems than younger children. This observation is in line with the literature on Western population samples, both traumatized and nontraumatized, also showing higher rates of symptoms in older than in younger children (Green, Korol, Grace, & Vary, 1991; Rescorla et al., 2007). Taken together, these findings might indicate a normative trend independent of trauma exposure. We did not find a significant Gender × Age interaction effect. This finding contrasts with findings of larger increases of symptoms with age for girls than boys in Western population samples (Rescorla et al., 2007; Twenge & Nolen-Hoeksema, 2002). Finally, in line with the literature on Western samples, children originating from families with higher SES were more likely to fall in the resilient group (Bonanno et al., 2007; Masten et al., 2009).

Based on the earlier literature on war-affected children, we expected trauma severity during abduction would be a crucial predictor of posttraumatic outcome (Mollica, McInnes, Poole, & Tor, 1998). However, both in our sample and in previous research on child soldiers, this was not the case (Bayer et al., 2007). Future research is required to investigate whether the assumed dose–response relation between trauma severity and posttraumatic outcome may not hold true for extremely exposed populations. This could be described as a threshold effect after which dose is so high that variation in dose no longer matters. In line with previous research on child soldiers, age at abduction and length of abduction were not significant predictors of posttraumatic outcome (Bayer et al., 2007; Derluyn et al., 2004).

Regarding additional trauma and life stressors, loss of parents was not a significant risk factor for resilience. Whether African extended family systems compensated for the loss of parents remains an open question. Domestic and community violence was identified as a significant risk factor for posttraumatic resilience. The return of children from the often extremely traumatizing experiences with the rebels to a violent and rejecting home environment may have led to an ultimate loss of trust in other people. There is some evidence that the exposure to war violence might brutalize societies and facilitate domestic abuse (Catani, Jacob, Schauer, Kohila, & Neuner, 2008). Therefore, violent behavior within families and communities might emerge as a long-term effect of warfare lasting beyond the end of armed conflict. Further research in domestic violence inflicted on children in postconflict countries is needed.

Person Variables

The frequent experiences of domestic and community violence may explain why perceived social support was not a significant predictor of posttraumatic resilience. In contrast, perceived spiritual support was a significant factor pertaining to resilience. Children who did not feel abandoned by God during crises showed significantly fewer symptoms. Spirituality and Christian religion are deeply rooted in social and cultural life of Northern Ugandans and may therefore be an important source of healing and reconciliation (Harlacher, Okot, Obonyo, Balthazard, & Atkinson, 2006). The LRA rebels target young children also because they are easily indoctrinated through redirecting their faith toward the rebels' aims (e.g., promising the children bulletproofing through spiritual rituals or forcing the children to commit atrocities while saying the name of God). The perception of God in Ugandan youth and the relevance of religion for coping with trauma need to be further investigated.

Dispositions (i.e., hardiness and positive future orientation) did not assist in explaining the variance in posttraumatic outcome. We employed a 10-item version of the CD–RISC (Campbell-Sills & Stein, 2007). Items such as "I can deal with whatever comes my way" are perhaps unsuitable for extremely exposed individuals such as child soldiers. It also is possible that the items of this scale may not reflect successful adaptation in children embedded in the Northern Ugandan culture.

Despite their severe trauma, children displayed high average scores of positive future orientation. This is noteworthy, as a negative future orientation (e.g., does not expect to have a career or a normal life span) has been described as an indicator of pathological trauma response (American Psychiatric Association, 2000). Although research is scarce, there are some indications of higher dispositional optimism in African populations (Eshun, 1999). Positive future orientation did not appear to play a protective role with respect to posttraumatic resilience.

Peritraumatic dissociation was not a significant risk factor for posttraumatic outcome. Understanding the function of dissociation in the process of trauma response in child soldiers requires further investigation. Dissociation is mostly used as a clinical concept and a predictor of subsequent PTSD (Diseth, 2005). Recent research, however, indicates that so-called emotional dissociation may protect extremely exposed individuals (Bonanno, 2004; Coifman, Bonanno, Ray, & Gross, 2007).

Our finding that revenge motivation was a risk factor for worse posttraumatic outcome is consistent with other research on child soldiers (Bayer et al., 2007). Moreover, when ruminating about someone who has caused them harm, people become more aggressive, which may translate into violent behavior (McCullough, Bono, & Root, 2007). Revenge motivation has been shown to be negatively associated with openness to reconciliation and forgiveness, also in child soldiers (Bayer et al., 2007; McCullough et al., 2001). Overcoming revenge motives may therefore be a crucial step toward sustainable peace building processes.

Further, children indicated that they frequently suffered from guilt, expressing that the time spent with the armed group caused them pain and suffering, and reported recurrent thoughts of their own acts being unjustified and unforgivable. In addition, survivor guilt may have played a role (e.g., guilt about surviving when others did not; American Psychiatric Association, 2000). Importantly, guilt was related both to being a victim of violence as well as to being a perpetrator (Table 2). Children had frequently been forced to torture or kill other individuals, sometimes even their relatives, to survive. The will to survive, obedience to orders, normalization of violence, and ideology may be the underlying psychological processes that enable children to become perpetrators (Wessells, 2006). Whether different psychological processes lead to guilt in victims versus in perpetrators is an interesting objective for future research. Responses to trauma, such as revenge and guilt, might sustain posttraumatic psychopathology in child soldiers as conceptualized in the cognitive model of the maintenance of PTSD by Ehlers and Clark (2000).

Limitations and Directions for Future Research

While the school presented a rare opportunity to assess a relatively large number of traumatized child soldiers in relation to potential risk and protective factors, the study had a number of limitations. We discuss six limitations, which may set directions for future research in this difficult environment.

First, we were not able to include positive behavioral outcome measures due to several methodological issues and logistic problems. For example, we had wanted to include academic achievement, but reports or remarks on students did not exist. Further, we were not able to obtain multiple perspectives on children's functioning, as parents were scattered throughout the northern part of Uganda and traveling was too dangerous. Teacher's perspectives could not be obtained as the classes were too big (60 students) to result in reliable data. Therefore we had to operationalize resilience, relying exclusively on the absence of symptoms. Clearly, our measures did not fully capture the individual differences in adaptation, motivation, and hope that we observed in these young people and that also are evident in the quotations we have included. Future studies should try to include positive indicators of adjustment (e.g., getting along with people, meeting expectations for chores or school, contributing to the community) and further investigate what defines resilience or an adaptive developmental outcome in ongoing- or postconflict contexts. Such a perspective needs to incorporate specific criteria for positive outcome for the various stages of child development (infancy and early childhood, middle childhood, and adolescence). In the developmental literature, positive outcome is often defined by successfully meeting age-related developmental tasks (e.g., early childhood: attachment to caregivers; middle childhood: school adjustment; adolescence: forming close friendships; Masten & Coatsworth, 1998). Suffering from posttraumatic psychopathology such as intrusive thoughts or depressive symptoms might hinder children in completing developmental tasks and therefore cause further psychological and social maladaptation.

Second, our study was cross-sectional, and we are not able to make any conclusions regarding stability and change in psychological well-being over time. Therefore, we could not distinguish between resilience, recovery, and delayed onset (Bonanno, 2004). Moreover, the onset of psychopathology may have not been posttrauma in some of the participating children. However, the duration and magnitude of symptoms within the different posttraumatic trajectories need further empirical investigation. Longitudinal research on child soldiers is urgently needed to answer these open developmental questions.

Third, for feasibility reasons, we used a convenience sample of former child soldiers. Having chosen a special-needs school for war-traumatized children might have biased the sample toward an overestimation of symptoms in child soldiers, as the admission process gave priority to extremely war-traumatized children. On the other hand, the special school may have boosted the prevalence of resilience in some of these young people. Additional research is needed with more representative samples and control groups.

Fourth, there were limitations in our assessment tools. We had to rely on Western-oriented questionnaires due to the lack of locally developed instruments. Another weakness was the single-item measurement of social and spiritual support, which presumably did not cover the constructs as a whole. It also was not feasible to include a full diagnostic assessment, and measures were limited to selected modules of the MINI–KID and the YSR. Thus, it is possible that some of the young people had symptoms and disorders that were not assessed by the measures used. Our research indicates the need for development and validation of cultural and context-sensitive measurements suitable for use in highly exposed populations. Assessment of cross-culture validity and reliability of standard psychiatric measurements are needed even without the usual "gold standards" (Bolton, 2001).

Fifth, our study focused on person variables. Certainly, familial (e.g., attachment, parenting) and social (e.g., friends) variables, as well as cultural factors (e.g., reconciliation ceremonies), may also be important influences on posttraumatic resilience. As recently suggested by Betancourt and Khan (2008), posttraumatic resilience needs to be understood from an ecological, developmental perspective that includes family, peers, schools, communities, and cultural and political belief systems. Within this approach, the roles of attachment relationships, caregiver health, resources and connection in the family, and social support available in peers and extended social networks need to be examined in war-affected children. Restoring damaged social ecology is fundamental to child development and psychological rehabilitation for war-affected children. Future research needs to integrate an ecological perspective.

Finally, it was not feasible to study resilience beyond the behavioral level. To understand the factors maintaining posttraumatic psychopathology, the neuroscience of posttraumatic stress may be important. Most research on the neurological underpinnings of PTSD identify the amygdala and hippocampus as key brain areas involved in the registration of potentially dangerous situations and in the later formation of memories of such events and cite the hypothalamic–pituitary–adrenal axis as a central agent in both the development of PTSD and its maintenance (Bremner, Elzinga, Schmahl, & Vermetten, 2008; Yehuda & LeDoux, 2007). Differentiating neurobiological correlates of PTSD and resilience following trauma exposure could contribute to explaining interindividual differences in trauma responses (Yehuda & Flory, 2007).

Implications for Interventions

Resilience research has a pragmatic mission, namely to provide principles of healthy development for successful intervention and treatment approaches (Masten & Coatsworth, 1998). Therefore, despite the scientific challenges posed by political instability in armed conflict situations, research is sorely needed to develop adequate measurements and tailored interventions. Our findings provide initial clues on factors to address in such programs. Domestic and community violence appeared to have a detrimental effect on the children's mental health over and above the traumatic events during abduction. Further, responses to trauma, such as guilt cognition, were negatively related to posttraumatic resilience. Moreover, it may be important to address revenge motives to break through the cycle of violence and work toward reconciliation.

While we focused on resilience, it is important to note that three in four child soldiers in our study were suffering significant levels of posttraumatic psychopathology. Interventional research in conflict areas is still scarce but very much needed. Cognitive behavioral treatment modules for the children (Onyut et al., 2005) as well as family-focused stress management programs may have beneficial effects on children and their family systems.

Our findings have implications for training and policy as well, because high levels of posttraumatic psychopathology in former child soldiers contrast with a psychiatrist-to-population ratio of 1:1.3 million in Uganda (Ovuga, Boardman, & Wasserman, 2007). Therefore, training of mental health professionals and a structural basis for sustainable intervention programs for children and adolescents in the region are urgently needed. Such programs should be based on knowledge on how to strengthen and sustain resilience in traumatized children.

Conclusions

Our findings indicate that despite severe trauma exposure, a critical proportion of former child soldiers showed a posttraumatic resilient outcome. Domestic and community violence, guilt cognitions, revenge motivation, and perceived spiritual support explained a substantial degree of variance in posttraumatic resilience over and above trauma severity during abduction. Knowledge of these factors provides initial clues on how to create interventions toward strengthening resilience in former child soldiers.

The present research benefited from two lines of research in the literature—one on resilience and one on trauma—that have not been fully integrated in research to date. Future research on severely traumatized children and adolescents would benefit from further integration of these perspectives, with the goal of an integrated paradigm of posttraumatic adaptation and resilience in ongoing- or postconflict contexts. Only through continued research on the processes leading to positive outcome can a full understanding of posttraumatic resilience be reached to inform intervention programs. The ongoing goal of research on posttraumatic resilience is to learn more effective strategies for protecting children and promoting their recovery from the developmental threats of trauma and violence.

The Kenyan Political Conflict and Children's Adjustment

Mumbe Kithakye and
Amanda Sheffield Morris

Andrew M. Terranova
Stephen F. Austin State University

Sonya S. Myers
Vanderbilt University

This study examined pre- and postconflict data from 84 children, ages 3–7 years, living in Kibera, Kenya, during the December 2007 political conflict. Results indicate that children's disaster experiences (home destruction, death of a parent, parent and child harm) are associated with adjustment difficulties and that emotion regulation is an important protective factor postdisaster. Specifically, severity of the disaster experience was associated with increased aggression and decreased prosocial behavior. Emotion regulation was associated with less aggression and more prosocial behavior postconflict. Findings are discussed in the context of a developmental, systems-oriented perspective of the impact of disasters on child adjustment.

While young children do not always present adult-like responses to disaster, exposure to disasters poses serious threats to the psychological and physical health of young children (for a review, see La Greca, Silverman, Vernberg, & Roberts, 2002; La Greca, Silverman, & Wasserstein, 1998; Lazarus & Cohen, 1977; McFarlane, 1987; Onyango, 1998; Ronen, 2002). In Sub-Saharan Africa, children below the age of 15 compose 44% of the population, and millions of these children are exposed to man-made disasters due to civil wars and political conflicts in the region (World Bank, 2007). In the year 2000, for example, 23 civil wars occurred worldwide, 10 of which took place in Sub-Saharan Africa (Bodea & Elbadawi, 2008). Researchers estimate that one in five people are negatively affected by armed conflict in Sub-Saharan Africa (Kimenyi & Ndungu, 2005). Yet, there is little research examining the effects of political conflict on the children's psychosocial adjustment. Drawing from a developmental, systems-oriented perspective (Wapner & Demick, 1998, 2002), the current article contributes to the field of disaster research by examining the impact of the Kenyan political conflict on children's psychosocial functioning, while considering children's preconflict adjustment.

Conflict in Kenya and the Current Study

Prior to 2007, Kenya was considered a nation with a low likelihood of conflict or civil war despite being surrounded by nations long involved in civil war. Sporadic clashes that did occur in Kenya were driven by land disputes, not lootable supplies or political purposes (Collier, Hoeffler, & Sambanis, 2005; Kimenyi & Ndungu, 2005). The political conflict that began shortly after the December 2007 presidential elections brought the nation closer to civil war than any other event since the nation's independence. The two primary candidates for presidency represented the largest tribes in Kenya, the Kikuyus and the Luos. Other major ethnic groups aligned themselves with either group based on historical ties and guidance from political leaders. This polarization led to acts of violence all over the nation, with the worst incidence occurring in the cities of Kisumu and Nairobi, and in Matharae and Kibera (two major slums in Nairobi). The conflict lasted close to 3 months and resulted in an estimated 1,000 deaths and over 100,000 internally

displaced children. Subsequently, close to 80,000 of these children remained in displacement camps for months after the conflict subsided (Majtenyi, 2008; United Nations Children's Fund [UNICEF], 2008). While most assistance given to families experiencing displacement focused on meeting children's basic needs, little attention was given to children's psychosocial adjustment as a result of these experiences (Kamatsiko, 2006). For this reason, the current study sought to examine changes in children's psychosocial adjustment following political conflict.

Although man-made disasters and natural disasters are generally related to similar psychological difficulties, understudied man-made disasters, such as the political conflict in Kenya, are important to study because political violence has specifically been linked to a variety of negative child outcomes (Sagi-Schwartz, Seginer, & Abdeen, 2008). Man-made and technological disasters have been linked to aspects of children's negative adjustment, such as a weakening sense of control, physical and emotional disturbances, somatic complaints, heightened aggression, fear, withdrawal, and posttraumatic stress symptoms (Davidson, Baum, & Collins, 1982; Gaffney, 2006; Sagi-Schwartz et al., 2008). The Kenyan political conflict occurred with little warning and lasted 3 months without a definitive ending point, characteristic of disasters which have been found to enhance negative consequences already associated with exposure (Baum, Fleming, & Davidson, 1983; Bolin, 1985; Davidson & Baum, 1986; Fritz & Marks, 1954; Lifton & Olsen, 1976).

Developmental, Systems-Oriented Perspective and Resilience

The developmental, systems-oriented perspective offers an ideal venue for examining the effects of disaster-related events, such as the Kenyan political conflict, on child functioning because its approach accounts for dynamic disruptions in person-in-environment systems that affect later development (Wapner & Demick, 1998). Broadly, the developmental, systems-oriented perspective asserts that individuals develop within an environmental context and that both the individual and environment interact at three levels of operation: physical, intrapersonal or interpersonal, and sociocultural levels (Demick & Wapner, 1988; Wapner & Demick, 1998). Whereas the physical level of the individual involves biological functioning and factors such as age, illness, and health, the physical level of the environment involves objects such as home destruction caused by disasters and relocation. The intrapersonal level of the individual encompasses psychological functioning such as attitudes, emotionality, and regulatory abilities, and the analogous level of the environment involves interpersonal factors such as peer and family relations. Sociocultural factors within the individual include factors such as gender, ethnicity, and one's role in society, and the sociocultural factors within the environment involve factors such as school and political transitions (Wapner & Demick, 1998).

Disasters (e.g., floods, hurricanes, terrorism, political conflicts) are thought to disrupt functioning at all levels of the individual and environmental systems (Wapner, 1987; Wapner & Demick, 1998), and these disruptions have been linked to psychosocial adjustment difficulties in children (Jones & Kafetsios, 2005; Moss et al., 2007; Qouta, Punamäki, Miller, & El-Sarraj, 2008; Rousseau, Drapeau, & Platt, 1999). However, not all children are negatively affected by disasters and political conflicts. This ability to positively adapt or mitigate the maladaptive reactions in the face of adversity is often labeled *resilience* (Luthar, Cicchetti, & Becker, 2000; Masten, 1994, 2007; Masten, Best, & Garmezy, 1990). Recent advances in the conceptualization and study of resilience suggest that the process of resilience can operate at and across multiple levels within dynamic systems (Masten, 2007). Thus, just as disasters can negatively impact individuals and their environments at physical, intrapersonal/interpersonal, and social levels, factors associated with these domains can also promote the process of resilience.

Physical Impact

Disasters, such as the Kenyan conflict, likely impact the physical level of the individual by causing physical harm and impact the physical environment by the destruction of homes, buildings, and property. Additionally, factors at the physical level, such as age, have been related to adjustment following disasters. A significant amount of research indicates that there is a dose–response relation between disaster exposure and adjustment (Klingman, 2002; La Greca & Prinstein, 2002; Lengua, Long, Smith, & Meltzoff, 2005; Moore & Moore, 1996; Silverman & La Greca, 2002; Yule & Williams, 1990), with direct and more severe disaster exposure (e.g., physical harm) leading to more adjustment difficulties. A critical review by Pfefferbaum et al. (2003) highlighted the importance of recognizing differences in the severity of exposure to disasters such as September 11, the Oklahoma City bombing, and the 1998 American embassy bombing in Nairobi, Kenya. Children directly exposed to the tragedies evidenced more trauma than those indirectly exposed.

Findings regarding age-related differences in reactions to disaster have been mixed but generally indicate that disasters negatively affect people of all developmental levels (for a review, see Bell, Greene, Fisher, & Baum, 2005; Silverman & La Greca, 2002). Some of the nonsignificant findings regarding developmental differences are likely the result of examining potential developmental differences in a narrow age range of participants, such as only focusing on children in late childhood (Vernberg, La Greca, Silverman, & Prinstein, 1996). One of the studies examining the broadest developmental range suggested the impact of disasters was greatest during middle adulthood (Thompson, Norris, & Hanacek, 1993). When focusing on the periods of childhood and adolescence, a curvilinear, inverted U-shaped association between natural disaster exposure and adjustment difficulties was discovered with adjustment difficulties increasing throughout childhood up until early adolescence and then decreasing into late adolescence (McDermott & Palmer, 2002). Most conflict researchers appear to consider narrow age ranges as well, emphasizing age-relevant impacts of conflict, such as child mortality among children below the age of 5, dropping out of school among school-age children, or sexual exploitation among adolescents (Barbara, 2000; Honwana, 2006).

Another feature of disasters, whether natural or man-made, is destruction of the home. Researchers are increasingly acknowledging the importance of home destruction to disaster victims. Findings indicate that home destruction negatively impacts individuals exposed to disaster, with higher levels of posttraumatic stress disorder (PTSD) symptoms and depression evidenced among those who experience severe or total home destruction (Gerrity & Steinglass, 2003; Goto, Wilson, Kahana, & Slane, 2006). Few studies have examined the effects of home destruction on children. An exception is Houlihan, Ries, Polusny, and Hanson (2008) who examined the impact of home relocation following a major tornado on children in Grades 3–12. Children in Grades 3–6 who relocated, due to severe home destruction, presented higher levels of internalizing behavior problems. Children in Grades 7–12 who relocated presented more externalizing behavior problems (Houlihan et al., 2008). Another study found that children whose homes were destroyed by a wildfire were at greater risk of posttraumatic stress symptoms (Jones, Ribbe, & Cunningham, 1994). More research is needed on child functioning following home destruction, particularly during political conflicts and war.

Intrapersonal and Interpersonal Factors

Disasters can also negatively impact children's socioemotional functioning by disrupting children's interpersonal interactions with their families because of parental harm, parental death, parental separation, or parental psychopathology. Additionally, intrapersonal factors such as children's abilities to manage their negative reactions likely mitigate some of the effects of disasters and promote resilience. Previous disaster research suggests that there are key adaptive systems that can affect outcomes of children facing threats, including attachment, social support within families and communities, and self-regulatory abilities. Self-regulation is particularly important to examine in relation to disaster events because being able to adapt and function in any situation requires aspects of regulatory control, such as determining/inhibiting actions, controlling emotions, and being able to focus attention in highly arousing situations (Masten, 2004). Indeed, self-regulatory abilities have been one of the more prominent factors investigated in the study of resilience and have been associated with more positive adaptation among children both during and following traumatic events (Eisenberg, Smith, Sadovsky, & Spinrad, 2004; Masten, 2007). Research suggests that children who cope poorly with disaster exposure and the resulting emotional distress suffer more severe stress reactions. Alternatively, children who effectively regulate their emotions are more resilient (Almqvist & Broberg, 1999; Kocijan-Hercigonja, Rijavec, Marusic, & Hercigonja, 1998; La Greca, Silverman, Vernberg, & Prinstein, 1996; La Greca et al., 1998; Shannon, Lonigan, Finch, & Taylor, 1994; Vernberg et al., 1996; Weems et al., 2007). It is likely that aspects of voluntary (i.e., effortful) self-control serve as protective factors in response to disaster exposure (Masten & Obradović, 2008). Despite the interest in the relation between self-regulation and resilience, there is little research on emotion regulation and adjustment following a disaster.

Emotion regulation involves components of temperament (e.g., affect, activity, and attention) typically defined in terms of the effortful processes that afford young children the ability to inhibit dominant responses and activate subdominant responses in times of stress (Eisenberg, Hofer, & Vaughan, 2007; Rothbart & Bates, 2006). One example includes inhibiting flight reactions and taking time to consider other responses, particularly in fear-arousing situations. In response to a traumatic event, emotion regulatory abilities allow children to shift their attention from distressing aspects of the event and inhibit maladaptive responses while still being able to process information related to the event (Lengua et al., 2005). In adults, improvements in regulatory abilities are related to the reduction in emotional and behavioral difficulties following exposure to war (Cloitre, Karestan, Cohen, & Han, 2002; Cloitre, Stovall-McClough, Miranda, & Chemtob, 2004), and emotion regulatory abilities protect children from long-term PTSD symptoms following disasters (Terranova, Boxer, & Morris, 2009).

Additionally, emotion regulation generally is associated with positive adjustment in young children because it enables them to react to specific environmental demands, or in the current context disaster experiences, with more positive adaptive responses (Eisenberg & Morris, 2002; Eisenberg et al., 2004; Eisenberg et al., 2007). Thus, more developed emotion regulatory abilities likely serve as a protective factor, making children more resilient to the adjustment difficulties commonly following exposure to disasters and political violence. It is important to note, however, that these constructs have been primarily studied in Western societies. Nonetheless, several conflict researchers have noted the possible role of children's regulation in coping, resilience, and functioning in times of war (Kostelny, 2006; Machel, 1996).

Intrapersonal characteristics contributing to positive adjustment following a disaster are often present prior to the disaster. However, due to the sudden and unexpected nature of most disasters, researchers rarely have the opportunity to examine the influence of predisaster intrapersonal characteristics on functioning. La Greca et al. (1998) reported high attention problems and low academic achievement prior to a disaster as risk factors for postdisaster stress symptoms. Other studies have found that children with more psychological difficulties prior to the disaster presented more symptoms of trauma, less coping skills and more behavioral problems following the disaster (McFarlane, 1987; Silverman & La Greca, 2002). Examining the relation between pre- and postdisaster adjustment may assist in identifying groups of children who are more likely to present poor adjustment following a conflict. Furthermore, the inclusion of predisaster adjustment allows for increased understanding of interpersonal factors associated with positive adjustment or the process of resilience postconflict.

Social support is another important interpersonal mechanism through which young children are impacted by trauma, with greater social support minimizing the negative effects of disaster exposure (e.g., Fleming, Baum, Gisriel, & Gatchel, 1987; Wapner & Demick, 2002). When parental health and functioning are negatively affected by a traumatic event, the support that parents are able to provide is limited. Child functioning is also likely affected as young children look to their parents to learn how to react to difficult or traumatic circumstances (A. S. Morris, Silk, Steinberg, Myers, & Robinson, 2007). Separation from a parent due to a disaster, parental harm, or even parental death are especially detrimental to children. Children who are separated from their parents experience more emotional distress during a natural disaster than those who are not separated (McFarlane, 1987; Silverman & La Greca, 2002). Similar findings are reported among children affected by war. Increases in aggression were reported among Israeli boys who experienced the death of their father due to war (Levy-Shiff, 1982). In South Africa, preschoolers displayed a variety of responses following detention of a parent for political reasons. Some children appeared more irritable, moody, and clingy during the detention, while others presented stomach aches and nightmares (Barbara, 2000). Particularly among young children, it is important to consider the ways in which family members, specifically parents, are impacted by natural and man-made disasters.

Sociocultural Impacts

A growing body of research also indicates that variations in postdisaster functioning are partially attributable to sociocultural factors, which include gender, socioeconomic status (SES), and ethnicity or culture (for a review, see Peek & Mileti, 2002; Silverman & La Greca, 2002). While the majority of the research supporting this statement is taken from natural disaster research (e.g., research about hurricanes, fires, or earthquakes), similar patterns are expected following political conflicts and other man-made disasters. Regarding the demographic characteristics of children, natural disaster research is sometimes mixed; however, some conclusions can be drawn. Generally, being female (e.g., Smith, Perrin, Yule, Hacam, & Stuvland, 2002; Vernberg et al., 1996; Weems et al., 2007) and of minority status (Brockerhoff & Hewitt, 2000; La Greca et al., 1996; Rabalais, Ruggiero, & Scotti, 2002; Shannon et al., 1994) are associated with more adjustment difficulties. Gender differences may be related to different propensities for psychopathology among males and females, but more research is needed to fully understand these differences, particularly among young children. Because males and females often differentially experience atrocities due to gender-based violence and sexual exploitation, gender is likely to be associated with differences in the experience of conflict. In the current study, child sex is examined as an indicator of child gender.

Disaster research also suggests that lower SES and related factors place minorities at increased risk of psychosocial difficulties (Bonanno, Galea, & Bucciarelli, 2007; Miller & Heldring, 2004). In the developing countries of Sub-Saharan Africa, the term *minority* is rarely used; nonetheless, the notion that groups of persons who represent a smaller proportion of the national population is relevant. Each of the 47 nations in Sub-Saharan Africa is home to many (∼ 30–500) different people groups or tribes. Due to ethnic diversity, nations are made of some groups that can be identified as majority groups and others as minority groups, with reference to numbers of people identifying with a specific ethnic identity. Majority and minority status, however, does not always reflect differences in SES or access to resources (Collier et al., 2005). In Kenya, ethnic minority status is often defined as either an "ethnic, linguistic, or political group" who lacks a dominant position, a group determined to preserve its ethnic identity in response to the larger society, or a group likely to be discriminated against due to their language, ethnicity, or religion (Makoloo, 2005). For example, groups may consider themselves in the minority due to the political dominance of one group at the expense of another (e.g., control of state, disbursement of favors to specific communities), religion-based persecution (e.g., discrimination and denial of rights), or on the basis of their way of life (e.g., pastoral vs. hunter-gatherer communities). Therefore, conflict difficulties may have less to do with ethnic group, or cultural identity and more to do with access to resources and location (Liddell, 1994). In the current study, we were not able to formally examine effects by tribal group as individual child group membership information was not collected. However, open-ended teacher responses on the impact of ethnicity or tribal status allowed some insight into the role of tribal group membership.

Current Study

Four months prior to the 2007 political conflict in Kibera, Kenya, data were gathered on children's socioemotional adjustment. Shortly after the end of the conflict, 3 months after the December 2007 elections, data were collected on the same children's postconflict allowing for a rare examination of the impact of politically related conflict on child functioning in Sub-Saharan Africa. Within this context, the current investigation utilized a longitudinal design to examine the impact of child and parental disaster exposure on children's postdisaster functioning (emotional symptoms, aggression, and prosocial behavior), while controlling for children's predisaster functioning. There is minimal research on children's psychosocial functioning following political conflicts in Sub-Saharan Africa, and most research has focused on physical health and mortality. The current study extends extant findings by examining changes in children's socioemotional adjustment (e.g., prosocial behaviors and internalizing and externalizing problems) following the Kenyan conflict. As has been reported in previous studies, a dose–response relation between disaster exposure and adjustment difficulties was expected. Specifically, we expected increases in emotional symptoms and aggression, and decreases in prosocial behavior, particularly among children who were more negatively impacted by the political conflict. Given the protective role of emotion regulation during adversity, it was expected that emotion regulation would act as a moderator between disaster experience and adjustment, such that children with better regulatory abilities would display fewer adjustment problems when exposed to disaster. Patterns of findings were also examined for sex and age differences.

Method

Participants

Pre- and postconflict data were collected on 84 children (46 female and 38 male) from their teachers ($n = 2$). Similar to the general ethnic breakdown in Kibera, participating children represented a broad range of ethnic backgrounds, including Kikuyus, Kambas, Luos, and Luhyas. At the start of the study, the mean age was 4.9 years ($SD = 1.23$) with 11% of the children identified as 3-year-olds, 27% as 4-year-olds, 21% as 5-year-olds, 20% as 6-year-olds, and 10% as 7-year-olds. All of the children resided in Kibera, one of the largest slums in Africa. Kibera is a densely populated area (estimated 800,000 people per 2 km^2) located in the capital city, Nairobi, of Kenya. Kibera is an informal urban settlement, characterized by high levels of poverty, inadequate access to safe water and sanitation, poor quality housing, and high levels of HIV/AIDS (United Nations Human Settlements Program, 2003). Residents of Kibera experienced especially high levels of postelection conflict in January and February 2008.

Measures

Severity of conflict experience. Due to the physical and logistical challenges of gathering data in Kibera, disaster severity data were collected only from teachers. As the teachers resided in the densely populated, close-knit community from which study participants resided, the teachers were well informed about children's conflict exposure and spoke with the children about their experiences. Teachers were asked to respond to several open-ended questions regarding the overall effects of the conflict on children and also provided responses to specific conflict exposure items for each child in order to asses children's individual level of exposure. The relevant items of conflict exposure included whether the child ''was separated from parent,'' ''was physically harmed,'' ''had a home destroyed,'' ''had a parent die,'' or ''had a parent physically harmed.'' Responses were coded a 1 if the child experienced the event and a 0 if the child did not experience the event. A disaster severity variable was created to reflect overall conflict experience by summing the values of the responses on the five disaster items presented above.

Child adjustment pre- and postconflict. Teachers reported on children's pre- and postconflict adjustment by completing the aggressive behavior, prosocial behavior, and anxious-fearful (emotional symptoms) scales of the Child Behavior Scale (CBS; Ladd & Profilet, 1996). Teachers responded to each item on a 3-point Likert scale ranging from *doesn't apply* to *certainly applies*. The scales have demonstrated good internal consistency (αs = .77–.96) and construct validity, particularly among children of different ethnicities and SES groups (Ladd & Profilet, 1996). In the current study, *aggression* was assessed via the aggressive behavior scale (seven items, $\alpha = .80$) using items such as ''kicks, bites, hits'' and ''taunts, teases.'' *Emotional symptoms* were assessed via the anxious-fearful scale (four items, $\alpha = .45$) with sample items such as ''is worried'' and ''cries easily.'' *Prosocial behavior* was assessed via the prosocial scale (six items, $\alpha = .81$) using items such as ''helps others'' and ''cooperative with peers.''

Child characteristics. Child age and sex were reported by parents and teachers prior to the conflict. Reports on children's *emotion regulation* were gathered postconflict via the effortful control scale of the Child Behavior Questionnaire–Shortened Scales (CBQ; Fabes, 1994; Goldsmith & Rothbart, 1991), which assesses a temperamental component of children's emotion regulation (Eisenberg & Morris, 2002). Teachers were asked to rate how true an item was for the child on a 7-point Likert scale (1 = *extremely untrue* to 7 = *extremely true*). Internal consistency estimates of the CBQ range from .67 to .94 (Goldsmith & Rothbart, 1991; see Fabes, 1994, for the reliability of the shortened scales), and scales from the CBQ have been correlated with similar observed constructs and child adjustment (Eisenberg et al., 1997). The effortful control scale is created by combining the attention focusing, attention shifting, and inhibitory control scales in an approach that has been used in prior research (e.g., Morris et al., 2002). Mean scores were created for each scale where higher scores indicate greater emotion regulation. The scores were then standardized and all three scales were summed creating the *emotion regulation* scale. The current study presented adequate reliability estimates for the combined scale ($\alpha = .66$ with 18 items). Sample items on this scale include ''is able to resist laughing or smiling when it isn't appropriate,'' can easily quit working on a project if asked,'' and ''is easily distracted when listening to a story'' (reversed).

Procedure

Children were recruited from a nursery school/day care center developed to serve the needs of the most vulnerable children either due to parental HIV/AIDS infection or death or due to extended periods of unemployment. Prior to the conflict, approximately 100 children attended the nursery school, 92 participated in Time 1 data collection, and 84 children participated in Time 2 data collection following the conflict. Data were collected through questionnaires completed by teachers at both Time 1 and Time 2. Teacher questionnaires were in English as the teachers are fluent English speakers. Preconflict data were collected by research assistants in Kenya, and postconflict data via mail, with directions and consent procedures also completed over the phone. For both pre- and postconflict data collection, Institutional Review Board approval was granted prior to data collection.

Results

Correlations and regression analyses were utilized to examine specific hypotheses, as outlined next. In addition to empirically testing hypothesized relations, teachers' responses to open-ended questions regarding the political conflict and the effect of the conflict on children's adjustment illustrate the role of ethnicity and describe the extent to which children were affected.

Descriptive Findings

Responses to specific exposure questions indicated variability in the disaster experience across the sample. Calculated percentages for the disaster variables indicate that: 43% had their home destroyed, 20% were physically harmed, 11% were separated from their parents, 13% had a parent die, and 26% had a parent physically harmed. Parent death was not included in parent harm or parent separation codes to ensure more independence among these variables. Thus, the percentages presented above reflect the percentage of individual children who experienced parental death, parental physical harm without counting harm leading to death, and parental separation not occurring as a result of parental death. Disaster severity was calculated a composite of the five disaster variables (coded 0 or 1), with a mean severity exposure score of 1.2 (see Table 1) in our sample and scores ranging from 0 to 4.

Teachers' responses to open-ended questions identified additional negative impacts of the conflict on children beyond those we had identified. Teacher 1 noted, "Several houses were torched and so children lack basic needs such as food, shelter, and clothing." Teacher 2 reported, "Some children were sexually harassed," and "Some children lost their close relatives." Teachers also observed increases in children's fear and negativity toward children in other tribal groups stating, "Most children have developed negative attitudes towards others and hence group themselves in tribal lines." No quantitative statistical analyses were performed using these data, as the open-ended questions assessed aggregate child functioning and experiences, intended solely for descriptive purposes.

Impact of Disaster Experience on Adjustment

We expected children's negative experiences during the conflict to be significantly associated with children's adjustment difficulties. In order to test this hypothesis, we examined correlations among disaster variables and adjustment postdisaster (emotional symptoms, aggression, and prosocial behavior). Child predisaster and postdisaster adjustment were not correlated, and predisaster adjustment was not associated with disaster experience variables; as such, the predisaster adjustment variables (emotional symptoms, aggression, and prosocial behavior) were not included in the correlation table (see Table 1). Regression analyses were conducted to examine the impact of disaster variables on postdisaster adjustment, controlling for predisaster adjustment, sex, and age of the child in each model. Although predisaster adjustment, sex,

and age were not significantly correlated with postdisaster adjustment or disaster variables, they were included in the regression analyses in order to control for predisaster adjustment. Separate models were computed for each adjustment and disaster variable, and for the composite disaster variable.

As expected, disaster variables were correlated with adjustment in expected directions, particularly prosocial behavior (see Table 1), with the exception of parental separation. Parental death was associated with greater emotional symptoms. Destruction of the home and overall disaster severity were associated with more aggression. Regression analyses examined changes in adjustment following the disaster experience. Regression models examined the contribution of each disaster variable (home destruction, parental death, parental separation, parent harm, child harm, and overall disaster severity) to child adjustment (emotional symptoms, aggression, and prosocial behavior) while controlling for child age, sex and the relevant predisaster adjustment variable (Time 1 emotional symptoms, aggression and prosocial behavior). All significant results reported in the current article represent an alpha level of .05 or below.

Unexpectedly, none of the disaster variables were significantly associated with emotional symptoms, controlling for predisaster emotional symptoms, age, and sex. For aggression, disaster severity, and home destruction, each predicted a significant proportion of variance in their respective postconflict aggression models. Home destruction, child sex, age, and preconflict aggression accounted for 17% of the variance in a significant model of postconflict aggression, $R^2 = .17$, $F(4, 73) = 3.78$. However, home destruction was the only significant predictor in the model, $\beta = .29$. Disaster severity, child sex, age, and preconflict aggression accounted for 17% of variance in a significant model of postconflict aggression, $R^2 = .17$, $F(4, 73) = 3.67$. Disaster severity was the only significant predictor in the model, $\beta = .28$.

For prosocial behavior, each disaster variable significantly predicted a proportion of variance in their respective postconflict prosocial behavior models. Home destruction, child sex, age and preconflict prosocial behavior accounted for 20% of the variance in a significant model of postconflict prosocial behavior, $R^2 = .20$, $F(4, 73) = 4.47$, with sex (0 = *male*, 1 = *female*), $\beta = .25$, and home destruction, $\beta = -.31$, as the only significant predictors in this model. Parent harm, child sex, age and preconflict prosocial behavior accounted for 24% of the variance in a significant postconflict prosocial behavior model, $R^2 = .24$, $F(4, 63) = 5.02$. Sex, $\beta = .33$, and parent harm, $\beta = -.38$, were both significant predictors in the model. Child harm, child sex, age, and preconflict prosocial behavior accounted for 19% of the variance in a significant postconflict prosocial behavior model, $R^2 = .19$, $F(4, 69) = 3.96$, with sex, $\beta = .27$, and child harm, $\beta = -.30$, as the only significant predictors. Parent death, child sex, age, and preconflict prosocial behavior accounted for 12% of the variance in a significant model of postconflict prosocial behavior, $R^2 = .12$, $F(4, 73) = 2.88$. Sex of the child was a significant predictor, $\beta = .24$, and parent death was a marginally significant predictor $\beta = -.20$. Disaster severity, child sex, age and preconflict prosocial behavior accounted for 30% of the variance in a model of postconflict prosocial behavior, $R^2 = .30$, $F(4, 73) = 7.90$. Sex of the child, $\beta = .25$, and disaster severity, $\beta = -.45$, were the only significant predictors in the model.

Impact of Child Characteristics on Adjustment

We hypothesized that children's emotion regulation would be associated with better adjustment postconflict and that emotion regulation would act as a moderator between disaster experience and adjustment, with poor emotion regulation exacerbating the effects of disaster severity. Potential moderating and direct effects of children's age and sex were explored as well. Moderation was tested according to Aiken and West's (1991) guidelines, and Holmbeck's (2002) procedures were used for probing significant interactions.

In both correlation and regression analyses, we found that emotion regulation was associated with postdisaster functioning. Specifically, emotion regulation was associated with less aggression and more prosocial behavior (see Table 1) even when controlling for participant sex, age, prosocial behavior preconflict, and disaster severity (see Table 2). Emotion regulation was not associated with emotional symptoms in correlation or regression analyses. Associations between disaster experiences and emotion regulation are also noted in Table 1, indicating poorer emotion regulation among children with more severe disaster experiences. As expected, emotion regulation moderated the link between disaster severity and prosocial behavior (see Table 3), but moderation was not found for aggression or emotional symptoms. Despite a marginal interaction, significant differences were found among children high and low in emotion regulation. Prosocial behavior was similar among children

high in emotion regulation regardless of disaster severity. Among children low in emotion regulation, disaster severity was associated with less prosocial behavior (see Table 3).

In terms of age and sex differences, age was not correlated with any adjustment variables. Sex of the child was correlated with postconflict prosocial behavior and aggression. Independent samples t tests indicated a significant difference in prosocial behavior, $t(82) = 2.60$, and aggression, $t(82) = 2.14$. Teachers reported more prosocial behavior and less aggression in girls compared with boys. Interaction terms were computed separately for sex and age and disaster severity (Sex × Disaster Severity; Age × Disaster Severity) in predicting adjustment. Neither interaction term predicted postdisaster adjustment, suggesting that differences in prosocial behavior and aggression were not influenced by an interaction between the sex or age of the child and overall disaster experiences. Nonetheless, child sex was a significant contributor to variance in child prosocial behavior, although the impact of disaster variables is similar among girls and boys.

Discussion

The paucity of research on children's postconflict adjustment in Sub-Saharan Africa is notable as the numbers of conflicts in the area continue to increase (Collier, 2006). As aid organizations search for ways to best assist children affected by conflict, the current investigation identifies person–environment variables that place children at increased vulnerability for poor functioning, indicating possible points for intervention. We found that parental death was associated with more emotional symptoms. Home destruction, disaster severity, and poor emotion regulation were associated with more aggression, even when controlling for predisaster aggression. We found strong links between disaster experiences and decreases in prosocial behavior as well. Home destruction, parent and child harm, parental death, poor emotion regulation, and overall disaster severity were associated with decreased prosocial behavior. Thus, our results support the premise that environmental level factors (e.g., home destruction) affect the child's ability to function following a disaster, and that the effect of the disaster experience on child functioning can be influenced by person level factors (e.g., emotion regulation).

Teachers' responses to open-ended items indicated changes in children's overall behavior (e.g., loss of appetite, fear) and their social behaviors in direct response to the conflict as well. For example, as reported above, one teacher described children as classifying and relating to one another based on tribe. This behavior is similar to observed adult behaviors during the conflict. Media reports of the conflict detailed attacks based on tribal lines (Majtenyi, 2008), and children were likely exposed to similar statements from family members. Children's aversion to sitting next to classmates from different tribes likely reflected the fear and prejudice adults were expressing. Thus, these findings suggest that increased awareness of tribal groups was a relevant aspect of the postconflict environment, although specific tribal membership was not examined.

Findings in the current study indicate that children who had more severe disaster experiences evidenced increases in aggression and decreases in prosocial behavior. These results are in agreement with other disaster studies that report higher levels of emotional problems and aggression among children exposed to a disaster (McFarlane, 1987; Silverman & La Greca, 2002; Wasserstein & La Greca, 1998; Weems et al., 2007; Yorbik, Akbiyik, Kirmizigul, & Sohmen, 2004). Findings also indicate that emotion regulation is associated with more prosocial behavior and less aggression postconflict. Despite little research into emotion regulation postdisaster among children, these findings concur with expectations of other researchers. For example, Lengua et al. (2005) suggested that children who had lower emotion regulation would show more adjustment difficulties following a disaster. Our findings indicate that emotion regulation abilities are associated with increased prosocial behavior and decreased aggression postconflict, even when controlling for preadjustment levels.

This study examined both child level and environmental factors that have been identified by researchers as potentially relevant to children's postdisaster functioning. The developmental, systems-oriented perspective asserts that aspects within the individual and aspects of the environment interact at multiple levels, and disasters can impact functioning at and across these multiple levels of functioning (Demick & Wapner, 1988; Wapner & Demick, 1998). Additionally, when studying disasters more specifically, Silverman and La Greca (2002) identified individual and environmental factors that play important roles regarding children's adjustment following disasters. Consistent with these perspectives, our findings suggest that child level factors interact with the context of conflict, in some cases exacerbating the impact of the disaster. We found that among children with poor emotion regulation abilities, disaster severity was associated with less prosocial behavior, whereas among children high in emotion regulation, disaster severity was not associated with prosocial behavior. These findings are consistent with recent research regarding the protective role of emotion regulation following natural disasters (Terranova et al., 2009). Recent conceptualizations of resilience include regulatory abilities as well as other protective factors interacting within a dynamic systems framework (Masten, 2007). Thus, subsequent research into adjustment following disasters should also examine potential protective factors from other domains, such as biological, family, community, and cultural factors.

J. Morris, van Ommeren, and colleagues recently acknowledged the need for empirical support of the child-relevant standards on mental and social health interventions in the most widely used humanitarian aid document, the Humanitarian Charter and Minimum Standards in Disaster Response (J. Morris, van Ommeren, Belfer, Saxena, and Saraceno, 2007; Sphere Project, 2004). They noted that minimal effort had been made to base child-related recommendations on empirical or theoretical findings. J. Morris and colleagues identified an immense need for further research examining the relevance of the recommendations for children, suggesting that empirically based research would contribute significantly to the ability of Sphere standards to present efficacious and beneficial intervention recommendations to children encountering disasters worldwide (J. Morris et al., 2007). As such, our examination of factors associated with children's adjustment postconflict may serve as a necessary step in the process of identifying opportunities for interventions that can be child focused, empirically supported, and universally applicable. For example, our findings support programs targeted at improving children's emotion regulation and increasing prosocial behavior postconflict.

There are several limitations in the current study that should be noted. A significant challenge involved choosing measures to assess children's socioemotional adjustment and conflict exposure. Although the CBS has been used in research in many different cultural and ethnic settings (Ladd & Profilet, 1996), research is lacking with children in particularly low-resource settings such as the informal human settlement of Kibera. However, high levels of associations between the scales in expected directions provide some validity for the use of the measure. The only variable that did not align with expected associations was emotional symptoms. As other studies have found significant associations between disaster exposure and preschool children's emotional symptoms (La Greca et al., 2002; McFarlane, 1987; Moss et al., 2007), the lack of findings for emotional symptoms in the current study is likely related to the low reliability of the emotional symptoms scale in the sample ($\alpha = .45$). Low reliabilities may be due to cultural differences in how behavior is described and what types of behaviors are socially acceptable. Generally however, associations between disaster experiences, child characteristics, and child outcomes all presented meaningful patterns, indicating construct validity despite the lack of prior support for use of measures. The items used to measure conflict were chosen to reflect disaster experiences researchers have identified as relevant to postdisaster functioning. By only allowing teachers to indicate whether the children experienced the different aspects of the conflict, we limited the expression of variability in children's disaster experiences. For example, the type of harm a parent experienced was not defined in the item asking whether the child's parent had experienced harm. The term *harm* could be interpreted in many different ways. We also were not able to examine whether the length of disaster experience or separation from a parent influenced child adjustment, as information on the length of separation was not collected. The combination of the exposure items to create a composite disaster severity variable allowed for some variability in disaster to be assessed. Study findings indicate that different aspects of the disaster may affect children in different ways. As such, further research could benefit from more specific descriptions of the disaster experiences.

Another limitation of this study is that teachers served as the only source of data in a restricted age group. With teachers as the only source of data postdisaster, detailed family-level information post-conflict was not available. This limited the ability to examine possible interactions between the child and family level factors. In addition, the only post-conflict family variables assessed were parental separation, death, and harm. Contrary to other disaster studies, parental separation was not associated with child functioning postconflict. A lack of findings may be due to the small numbers of children ($n = 9$) who experienced parental separation or the fact that a distinction was made between parental separation, death, and harm. Despite the absence of findings with parental separation, parental harm and death were associated with child post-disaster functioning, illustrating the importance of parent experiences and responses to postdisaster child adjustment. It also should be noted that the disaster variables are not independent. Many of the children experienced multiple disaster experiences (e.g., home destruction *and* death of a parent). Thus, findings for specific disaster experiences should be examined in light of this limitation. We chose to examine specific disaster experiences given little research on political conflict in Africa; however, the composite disaster findings are more robust to this limitation.

Results associated with age should be interpreted with caution in this study as well. While the sample of preschool and early school-age children provides a wider age range than most disaster studies, the low levels of literacy in the area leave some uncertainty in actual dates of birth for the children in the study, which were reported by parents predisaster. Sex differences in overall patterns of results also were not found. However, we did find differences in the levels of prosocial behavior and aggression. Further research should continue to examine the role of sex postdisaster as other studies have found more deleterious effects among females following disaster (Weems et al., 2007). It is possible that our lack of findings is due to a young sample that probably had similar conflict experience regardless of sex.

One important finding that emerged in this study was the decrease in prosocial behavior linked to disaster experiences and disaster severity. This is not surprising given rising social tensions among adults as a result of political and ethnic polarization; however, it is important to note that this tension was found among children. This is one of the first studies to our knowledge to examine prosocial behavior among children experiencing political conflict, as most disaster research has focused on negative functioning (e.g., aggression, PTSD, or internalizing problems). Our findings indicate that prosocial behavior is an important aspect of child functioning postconflict and that interventions should aim to increase prosocial behavior as well as decrease adjustment difficulties. This is in accordance with Machel's (1996) recommendation that supporting well-being may be more culturally appropriate in areas experiencing armed conflict, noting that the traditional therapy approach of having children talk about their experiences may not provide a cross-culturally appropriate means of coping with trauma (Machel, 1996).

This study provides some empirical support for specific intervention strategies following a political conflict. In line with other researchers and current disaster practices, all efforts should be made to protect children from physical harm during conflicts. In addition to physical difficulties, children who experience harm are more likely to present psychological difficulties following a conflict. The recent move to create ''safe spaces'' during a conflict that serve as an isolated, secure area where weapons are prohibited and children can play, may influence not only physical health but also psychological well-being following conflict (J. Morris et al., 2007; Sphere Project, 2004; UNICEF, 2002). Although we did not find a significant relation between parental separation and child adjustment, effects were found for parental death and harm. It is likely that intervening to strengthen parent functioning postdisaster and the protection of parents during conflict will influence child adjustment postdisaster. Finally, this study supports child-level interventions that support children's abilities to interact in appropriate ways and manage their emotional responses. Children who can control their emotional responses appear to adjust better following a disaster.

In this study, the focus is on children's functioning following political conflict. However, changes beyond the child can significantly influence children's functioning and resilience. Ngige (2008) identified five different levels of potential resilience stemming from her experiences working with war-affected children and families in Sudan: individual, extended family, community, national, and international. As the current study illustrates, resilience at the individual level (e.g., emotion regulation, prosocial behavior) is associated with children's functioning following political conflict. It is possible, however, to move beyond this level and inform our understanding of children's resilience more broadly by examining factors from other systems that impact children (Masten, 2007). A growing interest in how resilience is influenced by factors across systems provides future researchers with the ideal climate to examine factors at the family, community, national, and international levels (Masten & Obradović, 2008). Such findings have the potential to impact policy as well as intervention efforts. As one teacher illustrated with a comment written at the end of the survey, "As in the law of Rwanda, Kenya's constitution should force Kenyans not to classify others in terms of tribes, it should be a Kenyan and not Kikuyus, Kambas, or even Luos." Whether such behaviors can be enforced is beyond the scope of this study. Nevertheless, we can argue that in the same ways that adults' actions can harm children, children also can benefit from positive actions and policies undertaken on their behalf.

To evaluate whether conjoined maternal posttraumatic stress disorder (PTSD) and depression are associated with increased behavioral problems among terrorism-exposed preschool children (N = 116; 18–54 months), this study compared clinically significant child behavioral problem rates among the preschool children of mothers with PTSD and depression, depression alone, and neither disorder. Behavioral problems were independently rated by mothers and preschool teachers. Maternal depression and PTSD, relative to maternal depression alone, and to neither disorder, were associated with substantially increased child problems. Notably, maternal depression and PTSD were associated with increased emotional reactivity (relative risk [RR] = 5.9 by mother's and 3.4 by teacher's reports) and aggressive behavior problems (RR = 11.0 by mother's and RR = 5.9 by teacher's reports). This was corroborated by teacher ratings. Implications for intervening with terrorism-exposed preschool children are discussed.

Although preschool children are highly vulnerable to the effects of traumatic events, the effects of maternal psychopathology on preschool children exposed to terrorism are not as yet well understood (Chemtob, Nomura, & Abramovitz, 2008; DeVoe, Bannon, & Klein, 2006; Fremont, 2004; Laor, Wolmer, & Cohen, 2001; Pfefferbaum, 2005; Pine, Costello, & Masten, 2005; Thabet, Karim, & Vostanis, 2006).

Consistent with McEwen's (1998) allostatic load hypothesis, preschool children with conjoined exposure to World Trade Center (WTC) attack-related events and to other traumatic events have been found to be far more likely to develop clinically significant behavioral problems than children with WTC-attack exposure alone, or with other trauma exposure alone, compared to children without either type of trauma exposure (Chemtob et al., 2008). Clearly, exposure to the WTC attacks is likely to have also impacted the mothers of these children and may have caused some of these mothers to develop psychological disorders.

It is likely that very young children are affected by terrorism both as a result of the effects of direct exposure and, more indirectly, as a result of the impact of terrorism on their mothers' psychological functioning. However, little is known about whether maternal psychopathology associated with exposure to terrorism may be associated with increased rates of child behavioral problems.

Limitations of Current Research

The extant studies of the effects of maternal psychopathology on trauma-exposed children have tended to focus on older school-age children (cf. McCloskey & Walker, 2000; Najarian, Goenjian, Pelcovitz, Mandel, & Najarian, 1996; Smith, Perrin, Yule, & Rabe-Hesketh, 2001; Vila et al., 2001). Also, studies have usually confounded the effects of maternal and child event exposure (cf. Green et al.,

1991; Kilic, Ozguven, & Sayil, 2003; Wolmer, Laor, Gershon, Mayes, & Cohen, 2000). Moreover, research on the effects of disaster-related exposure on children has generally not distinguished the effects of disaster exposure from the effects of exposure to other lifetime trauma (cf. Chemtob et al., 2008), nor, to the best of our knowledge, have any of these studies specifically examined the effects of co-occurring maternal disorders on disaster-related child psychopathology.

In addition, nearly all the above studies relied on mothers as the sole informants about their preschool children. This reliance on mothers introduces a potential confound because of the possibility that maternal psychopathology would create systematic biases in the ratings of children's behavioral problems (Breslau, Davis, & Prabucki, 1988; Fergusson, Lynskey, & Horwood, 1993; Renouf & Kovacs, 1994). These maternal ratings of children may reflect the influence of their depression or posttraumatic stress disorder (PTSD) symptoms to an unknown degree and may result in rating biases. Teacher ratings are not necessarily more veridical than those of mothers, because teachers interact with children in a different context with different demands (Richters & Pellegrini, 1989). Nevertheless, examining both maternal and teacher ratings of child behavior would provide an opportunity to evaluate independent ratings of the child's functioning.

Finally, studies of the effects of maternal psychopathology on children have largely focused on maternal depression (Galea et al., 2002). To the best of our knowledge, no studies have directly contrasted the effects of maternal depression alone with the effects of co-occurring maternal depression and PTSD on terrorism-exposed very young children. Comparing the effects of maternal depression alone with the effects of conjoined depression and PTSD is potentially conceptually important. PTSD is a disorder in which the dysregulation of the response to threat is highly salient (Chemtob, Roitblat, Hamada, Carlson, & Twentyman, 1988; Yehuda, 2002). Chemtob et al. (1988) described the salience of threat detection as an attentional priming effect. The priming hypothesis has subsequently been empirically supported (Michael & Ehlers, 2007; Michael, Ehlers, & Halligan, 2005; Vythilingam et al., 2007). In addition, notably, there is evidence that women may have a lower threshold to threat appraisal compared to men (Olff, Langeland, Draijer, & Gersons, 2007). Thus, it can be expected that as a result of direct exposure to a direct threat to self and to child, a mother with PTSD will subsequently be more vigilant with respect to the presence of a possible threat and to have a lower threshold for identifying events as dangerous to herself, and to her child's safety.

Thus, a mother's PTSD can be expected to result in an increased emotional regulation burden for both mother and very young child (Hirshfeld, Biederman, Brody, Faraone, & Rosebaum, 1997) as the mother seeks to restore a sense of safety following exposure to terrorism. In short, a mother with PTSD may face a greater challenge in creating a sense of safety in her child because of her sensitivity—subtle or more overt—to potential danger. As a result, she may cue her young child to the presence of danger even when it is not present.

Depressed mothers may exhibit a lack of control over their environment, an inability to draw boundaries and inconsistency in disciplining their children (Kochanska, Kuczynski, Radke-Yarrow, & Welsh, 1987; Zahn-Waxler, Iannotti, Cummings, & Denham, 1990). They may also show more withdrawn or uneven affect and may have trouble interacting appropriately with infants and toddlers (Cohn & Tronick, 1989; Downey & Coyne, 1990; Murray, 1992; Stein et al., 1991). Thus, maternal depression is likely to be expressed through reduced maternal engagement with the child and reduced availability to the child, which may result in a lack of support for the child's emotional and behavioral regulation. Indeed, it has been suggested that infants who receive inconsistent responses from their caregivers may not develop the ego strength and ability to recover from the effect of negative interactions (Osofsky & Eberhart-Wright, 1988). Similarly, a depressed mother may be less attuned to the child's needs for contact, support, and encouragement. This suggests that the lack of availability of a depressed mother may restrict a child's ability to restore emotional and behavioral regulation following exposure to the threat of terrorism.

Thus, it could be argued that combined depression and PTSD might be expected to have a greater impact on a mother's ability to support her child's emotional and behavioral regulation. A mother's relative lack of availability (related to depression) to support her child's recovery, and her disposition to feeling unsafe and to overidentify potential threats (related to her PTSD) would compound the difficulty for a child of restoring his or her sense of safety after exposure to terrorism. This would then be predicted to result in increased problems in emotional and behavioral regulation, leading to a higher rate, and larger number, of child behavioral problems being associated with conjoined maternal PTSD and depression. Conversely, maternal depression *alone* may be sufficiently pervasive in its effects on child well-being in young children, because of its effects on attachment and child security, that the additional burden of maternal PTSD would have no added consequence for the child's ability to regulate emotion and behavior. In this instance, it would be expected that there would be no difference in rate, or number, of behavioral problems between the children of mothers with both PTSD and depression and the children of mothers with only depression relative to the children of mothers with neither disorder.

The Current Study

Accordingly, this study compared the impact of maternal depression alone to the effects of maternal depression and PTSD together on child behavior problems. We examined data from our study of the long-term impact of direct exposure to the WTC attacks on clinically significant behavioral problems in preschool children (Chemtob et al., 2008). In keeping with our interest in examining the relative effects of disaster exposure and lifetime exposure to other types of trauma, we had assessed maternal exposure to both the WTC attacks and to other trauma. We had also assessed maternal depression and PTSD. Finally, because a significant limitation of prior research on the impact of maternal psychopathology on very young children has been its reliance on single informants (usually mothers), we had obtained independent child behavior ratings from the preschool teachers of the children we studied. The teacher ratings provided the opportunity to obtain evidence from independent observers, who were not aware of the mother's mental state, about the children's behavior problems.

To address our primary question, we divided mothers into three groups: (a) mothers with neither disorder, (b) mothers with depression in the absence of PTSD, and (c) mothers with both depression and PTSD. We hypothesized that after removing the effects of child and mother exposure to the WTC attacks, and to other trauma, as well as demographic confounders, co-occurring maternal depression and PTSD would be associated with higher rates of clinically significant child behavioral problems compared to children of mothers with depression only, and compared to children of mothers with neither PTSD nor depression. We also hypothesized that the children of mothers with both depression and PTSD would have the highest number of clinically significant behavior problems. We focused on clinically significant behavior problems because they indicate child problems severe enough to be of possible public health significance.

Method

Participants

This study was reviewed and approved by the Mount Sinai School of Medicine's Institutional Review Board. It was conducted between March 2003 and December 2005 (a mean of 35 months after the WTC attacks) to assess the longer term impact of WTC-attack exposure on preschool children age 5 years or younger at the time of the WTC attacks. Families with children born between September 11, 1996, and September 11, 2002, were included if: (a) they lived in Lower Manhattan or (b) attended preschool or day care in Lower Manhattan on September 11, 2001 (the day of the WTC attacks). Families were recruited using extensive outreach in the Lower Manhattan area, primarily to preschools. (See Figure 1 for the geographical location of preschools relative to the site of the WTC attacks.)

After consent was obtained, mothers completed questionnaires about their child and themselves that included demographic information, exposure to the WTC attacks, exposure to other traumatic events, and emotional and behavioral functioning (see the Measures section). Children and mothers were assessed, and if symptomatic, they were offered free diagnostic and counseling services. The child's preschool teacher, who was blind to maternal report of the child behavioral problems and maternal psychopathology, also completed a questionnaire about the child's behavior. Teacher and parent questionnaires were administered independently from each other.

A total of 116 children and their mothers were included in the study (Chemtob et al., 2008). Three children of mothers who had PTSD only were excluded from these analyses, leaving 113 children. Participants who dropped out of the study did not differ on age, gender, race, or socioeconomic status (SES) from completers.

Measures

Demographics. Age, ethnicity of the child, and maternal education in years were reported by the mother. Children's age and time elapsed since the

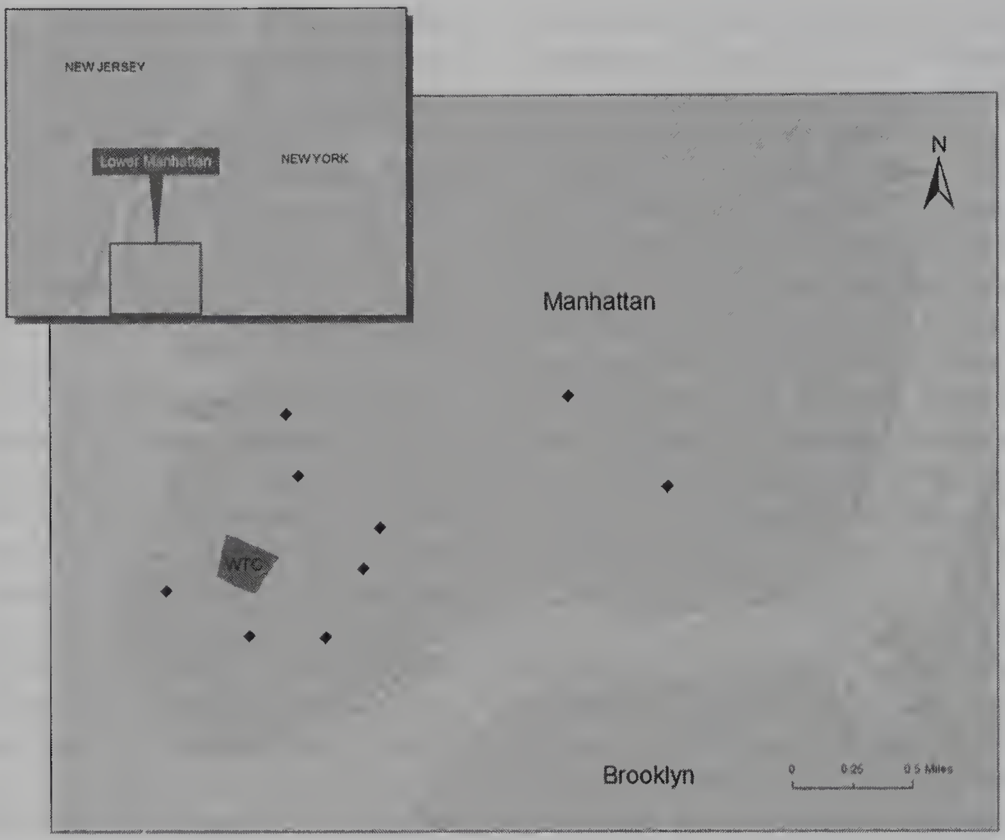

Figure 1. The geographical location of preschools relative to the World Trade Center (WTC).

WTC attacks were calculated based on the date of assessment, the child's date of birth, and September 11, 2001, respectively. SES was measured by maternal education, a reliable and valid index of SES (Bollen, Glanville, & Stecklov, 2007; Liberatos, Link, & Kelsey, 1988).

Maternal exposure to the WTC attacks and to other trauma. Maternal WTC-attack exposure was measured using the mother's dichotomous responses to six questions about direct exposure to high-intensity WTC-attack-related events. Respondents were asked whether they personally saw a plane hit a tower, saw the tower collapse, saw injured people, saw dead bodies, saw people jumping out of the building, and were caught in the debris or smoke. Responses to the six questions were summed to denote level of exposure. We used the trauma event checklist of the Posttraumatic Stress Diagnostic Scale (PDS) to measure lifetime history of other trauma exposure (Foa, 1995).

Child exposure to the WTC attacks and to other trauma. Mothers reported on the extent to which their children had been directly exposed to the WTC attacks. We created an index of child exposure to the same six high-intensity attack-related events. Child lifetime history of exposure to trauma other than the WTC attacks was measured using a modified version of the Traumatic Events Screening Inventory (TESI; Ghosh Ippen et al., 2002). The instrument measures exposure to traumatic events such as natural disasters, interpersonal losses, serious accidents, severe illnesses or injuries, animal attacks, exposure to war or terrorist acts, and exposure to suicide or attempted suicide.

Child behavior problems. Mothers used the preschool version of the Child Behavioral Checklist (CBCL/1.5–5; Achenbach & Rescorla, 2000), a widely used behavioral checklist with very good reliability and validity (Calkins & Dedmon, 2000; Gross et al., 2006; Mesman, Bongers, & Koot, 2001), to rate child behavior problems. In the normative study, test–retest reliability of syndrome scales of CBCL/1.5–5 ranged from .68 to .92 and it demonstrated good validity by its association with referral status of the child (Achenbach & Rescorla, 2000). Age and gender standardized *T* scores were calculated for the seven behavioral problem clusters (emotionally reactive, anxious/depressed, somatic complaints, withdrawn behavior, sleep problems, attention problems, and aggressive behavior). There were 5 children above the age of 5 at the time of assessment, 4 were 6 years old, and 1 was age 7. We followed the recommendation of the scale developer (Thomas Achenbach, personal communication, 2004) to use the preschool version of the scale for all the children in our sample. The preschool scale largely differs from the older child scale (CBCL 6–18; Achenbach & Rescorla, 2001) in that it omits a number of items particularly appropriate to adolescent children.

Preschool teachers, who were "blind" to maternal psychopathology and to the child behavioral ratings provided by mothers, completed the preschool version of the Teacher Report Form (TRF; Achenbach & Rescorla, 2000). The TRF behavior-rating checklist (Achenbach & Rescorla, 2000) parallels the CBCL and was designed for completion by teachers. The TRF has high test–retest reliability (mean $r = .81$) and good correlations with the CBCL (mean $r = .40$). The CBCL sleep problems cluster is not included in the teacher rating form of the CBCL.

Nevertheless, because sleep problems are associated with trauma exposure in children, and because they are of clinical importance, we present the parental ratings of sleep problems in Table 2 (see p. 1134). However, as this article is focused on using parent and teacher ratings, and because teachers do not rate sleep problems, the sleep problems cluster is not included in further analyses.

This article focuses on clinically significant preschool child behavioral problems. Scores ≥ 65 (93rd percentile) for the behavioral problem scales are considered clinically significant levels of problems for both the CBCL and the TRF. This cutoff was used to define clinically significant levels of behavior problems for both mother ratings and teacher ratings.

Maternal depression and PTSD. The Center for Epidemiologic Studies Depression Scale (CES–D: Radloff, 1977) was used to assess maternal depressive symptomatology. Probable maternal depression was dichotomized using the CES–D clinical cutoff score of 16, which is widely used (Breslau, 1985) for that purpose. The PDS (Foa, 1995) was used to measure maternal posttraumatic stress symptoms. The structure and content of the PDS parallel the *DSM–IV* PTSD diagnostic criteria (Foa, 1995). The PDS has a test–retest reliability kappa of .74 for PTSD diagnosis and convergent validity with a kappa of .65 with the Structured Clinical Interview (SCID) for *DSM–III–R*, with 82% agreement between the two measures (Foa, 1995). The sensitivity and specificity of the PDS with respect to SCID diagnosis is .89 and .75, respectively (Foa, 1995). Mothers were considered to have PTSD if they met all six diagnostic criteria—exposure to a traumatic event, persistent reexperiencing symptoms, persistent avoidance of the stimuli associated with the trauma, persistent arousal, duration of the disturbance for longer than 1 month, and clinically significant functional impairment.

Statistical Analysis

The major analyses are based on grouping the mothers according to whether they had: (a) neither depression nor PTSD, (b) depression alone, or (c) both depression and PTSD. Based on this subdivision, we first compared relevant demographic and trauma-exposure characteristics to detect potential confounding variables. Analyses were performed first based on mother's report. Confirmatory analyses were then conducted based on the behavioral ratings of teachers. Mother and teacher reports of child behavior were entered as dependent variables in separate models.

To examine the rates of clinically significant child behavior problems by maternal psychopathology, univariate analyses were conducted using chi-square tests for overall group difference followed by chi-square linear-by-linear association, also known as the Mantel Haenszel chi-square test (Dosemeci & Benichou, 1998; Hakulinen, 1981) for overall trend to evaluate a dose–response relation between maternal psychopathology groups (neither, depression only, and both depression and PTSD) and each child behavioral problem cluster.

Next, to examine the risk for each behavioral problem in children of mothers with PTSD and depression and in children of mothers with depression alone, hierarchical logistic regression was performed after creating two dummy variables for maternal psychopathology: (a) for mothers with depression only and (b) for mothers with both depression and PTSD. The group of mothers with neither PTSD nor depression served as the reference group. The effects of potential confounders described earlier were first included before the two dummy variables for maternal psychopathology group were entered in the model. The risk of having each behavioral problem (emotionally reactive, anxious/depressed, somatic complaints, withdrawn behaviors, aggressive behaviors, and attention problems), as measured by odds ratio, for children of mothers with only depression and children of mothers with comorbid depression and PTSD, as compared to the reference group, based on mother's and teacher's report, was first obtained. As odds ratio is only an approximation of the relative risk and could be inflated due to high occurrence of the problems, we converted our odds ratio into relative risk. We have used the converting formula presented by Zhang & Yu (1998):

$$RR = \frac{OR}{(1 - P_0) + (P_0 \times OR)},$$

where P_0 indicates the incidence of the outcome of interest in the nonexposed group (i.e., children of mothers with neither depression nor PTSD). Ninety-five percent confidence intervals (CI) were also converted, accordingly.

As children were drawn from 10 different preschools/day-care centers, and some were from the same family (*n* = 13), the assumption of independent observations underlying standard errors and CIs may be violated. To account for data clustering, standard errors for rates of behavioral problems were computed using the Taylor series linearization method, while standard errors and CIs for parameters estimated from the logistic analyses were computed by using the method of weighted maximum likelihood, adapted for survey and clustered data through implicit Taylor series (Binder, 1992; Lin & Wey, 1989). Missing data were handled through listwise deletion. There were no missing data on the key study variables and minimal missing data in the control variables: child exposure to trauma other than 9/11 related (*n* = 2, 1.7%) and maternal education (*n* = 8, 6.9%).

Finally, as shown in Figure 3 (see p. 1136), we counted the number of clinically significant behavioral problems rated by mothers and by teachers for each child. One-way analyses of covariance (ANCOVAs; with child age, maternal education, and time passed since the WTC attacks used as covariates) were conducted separately for mother and teacher ratings. We normalized the outcome variables (number of behavioral problems based on mothers and teachers reports) by logarithm transformation to satisfy the assumptions of normal distribution and heteroscedasticity, that is, a condition where the variances of dependent variable are not equal for every value of predictor or grouping variable (Kotler & Brown, 1990; Schmidt, 2000). Because we used logarithm-transformed values in our analysis to remove heteroskedasticity, the numbers reported were transformed back in the original integer scale. We provide the *F* statistics from the ANCOVA based on both the transformed and nontransformed variable. We present the diagram (Figure 3) that shows the mean number of clinically significant behavioral problems among different maternal psychopathology groups based on nontransformed outcome values, as they were very similar and some readers may find the nontransformed means more clinically meaningful.

Results

Table 1 presents participant characteristics by maternal psychopathology category. There were no differences in age, gender distribution, maternal education, or exposure to the WTC attacks. However, mothers with depression and PTSD, and their children, were significantly more likely to have experienced other traumatic events. Approximately, 12% of the children in the sample met criteria for clinically significant emotionally reactive behaviors and for somatic complaints, 10% for anxious/depressed, 9% for withdrawn behavior and for attention problem, and 8% for aggressive behavior clusters.

Table 1
Characteristics of Participants by Maternal Psychopathology Group

	Maternal psychopathology group		
	Neither (*n* = 75), *M* (*SE*)	Depression (*n* = 24), *M* (*SE*)	Comorbid (*n* = 14), *M* (*SE*)

[a] A score of 65 or more on each Child Behavioral Checklist cluster was used to indicate behavioral problem symptoms. Depression is defined as scores above 16 on the Center for Epidemiologic Studies Depression Scale; PTSD is defined as positive on all six symptom clusters indicated by the PDS. [b] Fisher's exact test was applied for chi-square statistics when at least one of the cells had ≤ 5 observations. [c] Chi-square linear-by-linear association is used to evaluate whether rate of behavior problems increases in a dose–response fashion.

Table 2 presents the rate of each behavioral problem cluster in children, based on mother's report. When the rates of behavioral problems in children associated with each of three groups of mothers were compared, there were significant differences for all child behavioral problem clusters, except for withdrawn behavior and attention problems. There was a significant dose–response relation (i.e., where dose is defined as the number of maternal diagnoses) for all child behavioral domains, except withdrawn behavior. When the analyses were repeated using teacher reports, we found that the rates of child behavior problems associated with the maternal psychopathology groups were similar to those found based on the mother ratings of the children. However, teachers reported observing fewer child somatic complaints and more aggressive behavior. For teachers, as seen in Table 3, a significant dose–response relation in emotionally reactive, aggressive behavior, and attention problems was found. Fisher's exact test was applied in all analyses.

To confirm the increased risk based on maternal psychopathology category, a multiple logistic regression was performed. To minimize bias due to multicollinearity between mothers' and children's exposure to other trauma and maternal psychopathology group, first we entered potential confounders, including a priori determined demographic confounders and mothers' and children's exposure to the WTC and other trauma and then entered maternal psychopathology dummy variables in the model. Figure 2 presents the relative risks (RR) based on the mothers' ratings and the teachers' ratings of child behavior side by side. Whiskers at the end of the bars represent standard errors. Compared to the reference group of children of mothers with neither depression nor PTSD, depression and PTSD occurring together significantly increased the risk for aggressive behavior (RR = 11.0), emotionally reactive (RR = 5.9), anxious/depressed (RR = 4.8), and somatic complaints (RR = 4.1). In contrast, there was no significantly increased risk for behavioral problems in children of mothers with only depression with the exception of somatic complaints (RR = 3.4).

Similar patterns were observed across rater type (mother, teacher) in emotionally reactive behavior and aggressive behavior. However, teachers were more likely to observe problems in withdrawn behavior (RR = 9.0, p = .006) among the children of mothers with depression and PTSD. Based on mothers reports, significant increased risk of somatic complaints were reported in children whose mothers had both PTSD and depression (RR = 4.1, p = .03) and children whose mothers had only depression (RR = 3.4, p = .04), whereas no significant increased risk was reported based on teachers report.

Finally, as shown in Figure 3, we present the mean number of clinically significant behavioral problems (i.e., nontransformed), as rated by mothers and by teachers for each child. One-way ANCOVA (with child age, maternal education, and time passed since the WTC attacks used as covariates) shows that there was a significant difference in number of child behavioral problems by mater-

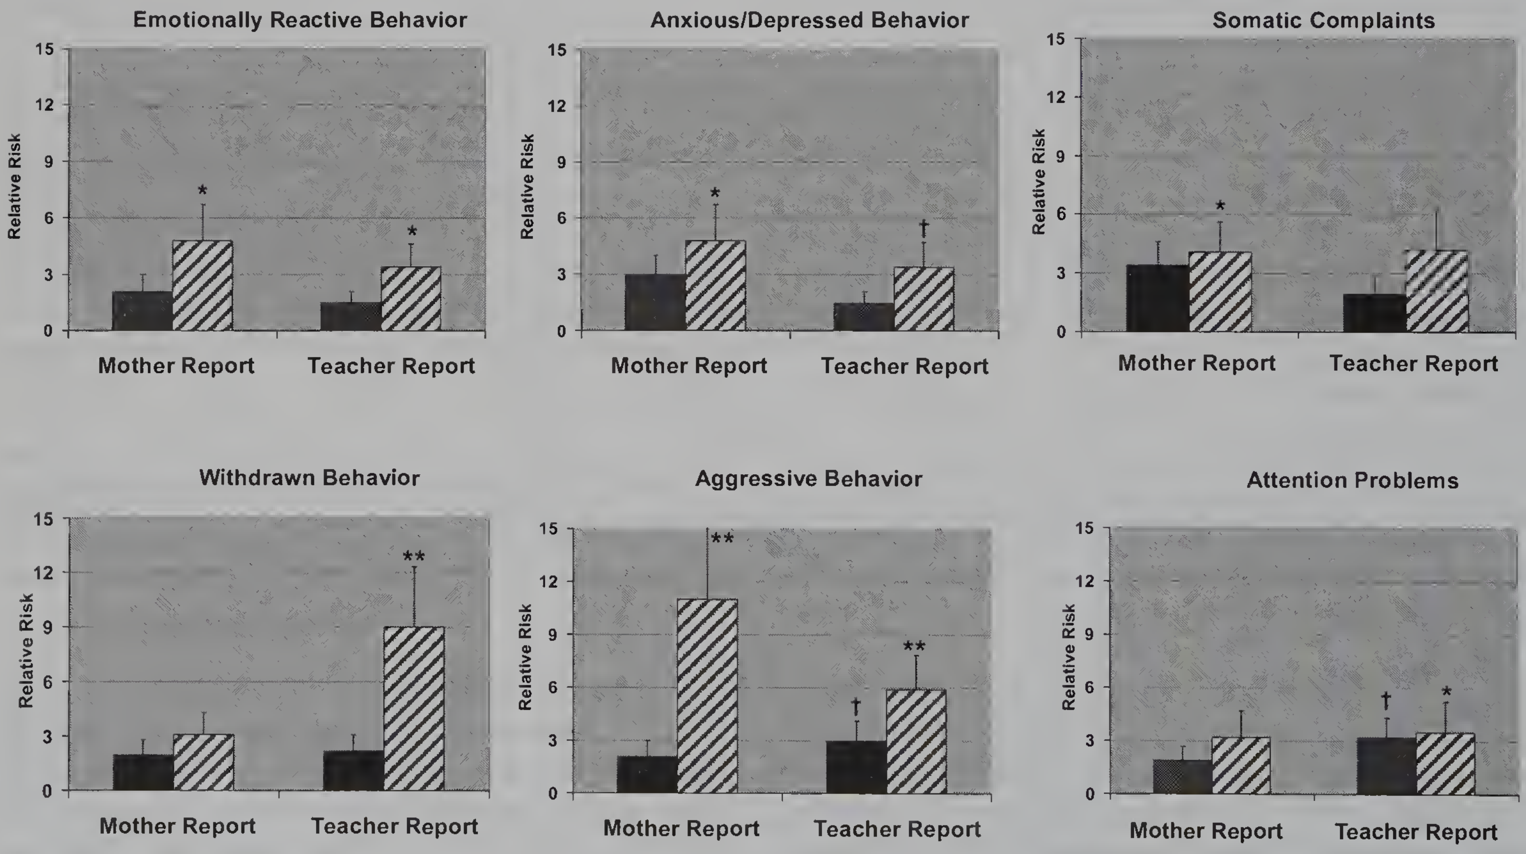

Figure 2. Risk for behavioral problems in children of mothers with only depression and with both depression and posttraumatic stress disorder (PTSD), based on mother's and teacher's reports.

Note. Striped bars represent both PTSD and depression. Bars with block print represent depression only. Risk in two groups (depression only and PTSD and depression) was calculated relative to that in children whose mother had neither depression nor PTSD. The effects of exposure to the World Trade Center and other trauma as well as potential confounder effect were statistically adjusted for in multiple logistic regression model.

$^{+}p < .10$. $^{*}p < .05$. $^{**}p < .01$.

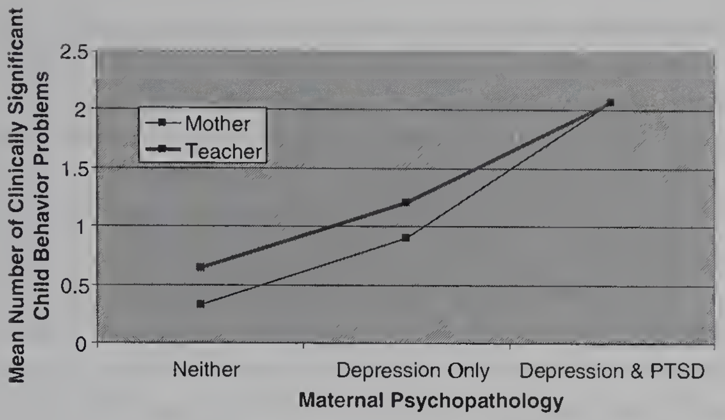

Figure 3. Mean number of clinically significant child behavior problem clusters (as rated by mothers and teachers) by maternal psychopathology group.

nal psychopathology category, and by mother's report based on nontransformed outcome variable, $F(2, 110) = 15.1$, $p = .001$, and transformed outcome variable, $F(2, 110) = 4.1$, $p = .002$. There was a similar significant difference in number of child behavioral problems by maternal psychopathology category by teacher's report based on the nontransformed outcome variable, $F(2, 96) = 5.4$, $p = .006$, and the transformed outcome variable, $F(2, 96) = 3.7$, $p = .004$. Post hoc testing, based on the transformed outcome variable, demonstrated that children of mothers with depression alone had a larger number of behavioral problem clusters that met clinical significance than children of mothers with neither PTSD nor depression, rated by the mother ($p = .04$). Children of mothers with both depression and PTSD had a significantly larger number of behavioral problem clusters that met clinical significance criteria than children of mothers with depression alone, rated by mother ($p = .04$) or by teacher ($p = .03$). A test of the difference between the regression slopes associated with each informant type showed no significant difference ($p = .78$).

Discussion

This study has three main findings. First, the children of mothers with co-occurring probable depression and PTSD had the highest rate of clinically significant behavior problems compared to children of mothers with depression and to the children of mothers with neither disorder. Second, the linear-by-linear association analysis showed a significant dose–response relation in emotionally reactive, aggressive behavior, and attention problems in their children, based on both mother's and independent teacher's reports. Mothers' reports additionally showed a dose–response relation in anxious/depressed and somatic complaints in their children. Third, similarly controlling for child and mother trauma exposure, children of mothers who had depression and PTSD were found to meet the cutoff for clinical significance for a larger number of behavior problem clusters, as rated by both mothers and teachers. Maternal and teacher reports were strikingly concordant in this regard highlighting that the differences in rates of child behavioral problems by maternal psychopathology grouping were not due to rating biases associated with maternal psychopathology.

Emotionally reactive behavior problems and aggressive behavior problems appear to be the most saliently associated with co-occurring maternal PTSD and depression. Notably, they are also the behavioral problems on which mothers and teachers have the highest observed concordance. The emotionally reactive behavior cluster indexes emotional regulation (Achenbach & Rescorla, 2000), whereas the aggressive behavior cluster indexes the behavioral regulation of outer-directed negative behaviors (cf. Barkley et al., 2000; Calkins & Dedmon, 2000; Shaw, Owens, Giovannelli, & Winslow, 2001). These two behavior clusters are of high public health significance. The results suggest that co-occurring maternal depression and PTSD interfere substantially more with the mother's ability to assist her young child in accomplishing the tasks associated with emotional and behavioral regulation than maternal depression alone.

Our findings may be interpreted either as consistent with the proposition that having two diagnoses is generally more impairing for mothers than having one, or to the additive but different effects of maternal PTSD and depression. The question of differential effects of maternal "dose" or "type" of psychopathology should be pursued in future studies. Little is known about whether a mother having co-occurring PTSD and depression results in greater generalized maternal impairment and reflects a nonspecific additive burden (a greater dose) or alternately whether maternal PTSD and depression each interfere with specific maternal functions and result in greater impact on the child because multiple maternal functions are affected (type). To illustrate, a depressed mother may be selectively unable to praise positive behavior in her child. A mother with PTSD may selectively respond to potential threat in her child's play and increase the child's anxiety. A mother with depression and PTSD may be so affected by her own distress that she is generally unavailable to her child, reflecting a generalized effects of dose (number of psychopathologic problems), or she may be both unable to praise positive behavior, reducing her support for child's positive coping and selectively overrespond to perceived threats increasing her child's anxiety. This latter possibility would suggest specificity (type) effects related to maternal PTSD and depression. The question is further complicated because children may react with specific behavior problems in association with specific maternal problems. However, it is also possible that they would have more problems in general as maternal number of problems increases without specific expression, reflecting whether the mother has depression, PTSD, or both.

These are important questions for further research with traumatized very young children and their mothers to explore. Such studies would be materially advanced by incorporating observational studies of dyadic interaction. Indeed, if there are different patterns of dyadic interaction associated with conjoined PTSD and depression, compared to the other two groups, and these dyadic interaction differences are associated with distinct child behavioral problems, this would suggest that specific behavioral problems in offspring may have different etiologies and modes of transmission. Similarly, it would be useful to examine biological markers associated with the intergenerational transmission of traumatic stress vulnerability (Yehuda & Bierer, 2008). Although they are highly informative, the data on which this study is based do not allow us to address the question of how maternal depression and PTSD specifically exert their effects on preschool children, and this remains an important research frontier.

Study Limitations

Although cross-sectional in design, our study included consideration of the effects of maternal and child lifetime history of other trauma exposure. This aspect of trauma exposure has not previously been taken into account systematically to the best of our knowledge. Our findings are strongly buttressed by the concordance of independent ratings of child problems by parent and teacher. Future studies should further extend these descriptive findings by including observational and behavioral measures to characterize differences among children and mothers in more specific detail. Also, future studies should specifically examine possible differences in dyadic interaction between child and mother that might be associated with maternal psychopathology. Such observational and behavioral studies may help elucidate mechanisms that distinguish the effects of conjoined depression and PTSD from those of maternal depression alone. We assessed maternal PTSD and depression using well-validated self-report measures. Nevertheless, future studies should also include SCIDs that assess the full range of maternal psychopathology, in consideration of possible contributions of other maternal psychopathology, than PTSD and depression to preschool children's behavior problems.

The primary purpose of this study was to assess the relative impact of maternal depression alone versus conjoined maternal depression and PTSD on child behavior problems. Future studies can extend these findings by comparing the effects of maternal PTSD alone with the relative effects of maternal depression alone. This study could not illuminate whether maternal depression existed prior to exposure to the WTC attacks. In addition, this study focused on maternal depression and PTSD as categorical variables and examined their association to clinically significant behavior problems in preschoolers (also a categorical variable). Thus, this study's focus addressed itself to the effects of clinically significant maternal psychological problems on clinically significant child behavioral problems. Future studies will address the associations of maternal PTSD and depression and preschool child behavioral problems using continuous measures of symptomatology and child behavior problems.

Studies of child and maternal vulnerability prior to exposure to terrorism and disaster would help clarify the interaction of vulnerability and exposure. Similarly, the design of this study could not address whether maternal PTSD alone might have been found more frequently closer in time to the actual exposure to the WTC attacks among these mothers of young children. Answering these types of questions would require the use of prospective longitudinal designs. In short, an important focus for future research should be to characterize the course of natural recovery of mother and child over time, ideally considering preexposure vulnerability, and examining dyadic interaction patterns. Finally, although these findings point to the importance of maternal psychopathology in the behavioral outcomes associated with terrorism exposure in preschool children, we cannot be certain that our results will generalize to other types of terrorism attacks (chronic and recurrent; other types of smaller impact single events) and to the effects of other disasters.

Clinical Implications

These data strongly suggest that very young children are vulnerable to the effects of terrorism and, given the time of assessment postexposure, that these behavioral effects are persistent. Yet, it appears that young children were provided services far less than other populations following the WTC attacks (Covell et al., 2006). We previously recommended that one strategy to increase efficacy in identifying children at need of services would be through screening by pediatricians (Chemtob et al., 2008).

The present findings suggest that a complementary strategy to identify very young children at risk is through identifying psychopathology among the mothers of very young children in the aftermath of large-scale disasters. Moreover, particular attention should be given to identifying mothers with co-occurring depression and PTSD when developing a strategy to identify very young children who are at risk subsequent to terrorism exposure. Given the apparent persistence of the effects of terrorism, interventions need to consider multiple stressors faced by both mothers and children over time (Appleyard & Osofsky, 2003; see also Chemtob et al., 2008, as recovery from exposure to terrorism occurs over time in the context of often challenging postdisaster recovery environments.

Screening and intervening with the mothers of young children may serve to help both mother and young child more efficaciously. In this regard, our findings add to the growing literature pointing to the importance of considering the mother–child dyad in conceptualizing the effects of trauma as well as its treatment especially when very young children are involved (Chemtob et al., 2008; Lieberman & Van Horn, 2005; Schechter et al., 2002). Promising data have indicated that dyadic intervention can enhance the well-being of both mother and young child following domestic violence exposure (Lieberman, Ghosh Ippen, & Van Horn, 2006). There is a need for dyadic interventions that target supporting young children and their mothers following exposure to terrorism and disaster. As well, Weissman has shown that treating maternal depression alone can have a salutary effect on child symptoms (Weissman et al., 2006). There is certainly value in pursuing both dyadic and mother-centered treatment research that focuses on ameliorating outcomes for mothers with conjoined PTSD and depression and their young children following exposure to terrorism and to other types of disaster.

Exposure to 9/11 Among Youth and Their Mothers in New York City: Enduring Associations With Mental Health and Sociopolitical Attitudes

The enduring impact of exposure to the 9/11 terrorist attacks on mental health and sociopolitical attitudes was examined in a sample of 427 adolescents (M = 16.20 years) and their mothers residing in New York City. Direct exposure to the terrorist attack was associated with youth depression symptoms and with mothers' posttraumatic stress disorder symptoms. There was no evidence of reciprocal effects of mother exposure on youth or of youth exposure on mothers. Although mothers reported engaging in more emotional processing coping assistance with their children, coping assistance was not associated with youth's symptomatology. Media exposure was found to be a strong predictor of youth's and mothers' sociopolitical attitudes about issues such as prejudice toward immigrants, social mistrust, and current events.

It is not an exaggeration to say that nearly everyone in the United States was affected in some way by the September 11, 2001, terrorist attacks on New York City (NYC) and Washington, DC. The dramatic events of 9/11 were reasonably expected to have far-reaching and long-lasting effects on the mental health of adults and children throughout the United States. Yet, undoubtedly those individuals who witnessed the attacks and their aftermath first-hand will have been especially affected by the event. Without any form of warning, lower Manhattan was transformed into a disaster zone when terrorists attacked the World Trade Center (WTC) on 9/11. The scale of the devastation and the large number of victims meant that residents throughout NYC were directly affected. Individuals throughout the city had direct exposure to the 9/11 attacks by physically being at or near the WTC, by seeing the towers in flames or collapsing, by smelling the cloud of smoke that hovered over the city for days, or by having their day severely disrupted by lack of subway and bus transportation or by the pandemonium that waged throughout the city as residents worried if another attack was imminent and tried to reach their loved ones through clogged phone lines. Indeed, in the months following the attack, New Yorkers initially exhibited high rates of posttraumatic stress disorder (PTSD), with estimated rates of between 7.5% and 11.2% of probable PTSD among adult residents (Galea et al., 2002; Schlenger et al., 2002) compared to a rate of 5.8% among a national sample of Americans 6 months after the attacks (Silver, Holman, McIntosh, Poulin, & Gil-Rivas, 2002). A study of a representative sample of NYC school children 6 months after 9/11 determined that 28% of the students had one or more anxiety or depressive disorders and that

---

We wish to thank the collaboration among the New York City Department of Education, Applied Research Consulting LLC, Columbia University Mailman School of Public Health, and New York State Psychiatric Institute for allowing us to use their measure of the impact of 9/11 on New York City public school children. We also wish to thank Irene Strum and Henry Solomon at the New York City Department of Education for their assistance in maintaining contact with this longitudinal sample, and to thank Jim Mercy and Rodney Hammond in the Division of Violence Prevention at the Centers for Disease Control and Prevention for helping secure supplemental funding for a module of questions related to 9/11. This work was conducted while the authors were employed at the National Center for Children in Poverty, Mailman School of Public Health, Columbia University, and was funded through grants from the Centers for Disease Control and Prevention through the Columbia Center for Youth Violence Prevention (CCR218598) and from the National Institute of Mental Health (1R01MH63685) awarded to the first and second authors.

greater exposure to 9/11 was associated with greater levels of problematic mental health symptoms (Hoven et al., 2005). In this article, we examine whether exposure to the 9/11 attacks had enduring effects on a sample of youth and their mothers residing in NYC.

Parents are typically more negatively affected by a disaster than are nonparent adults (Norris, Friedman, Watson, Byrne, et al., 2002) and thus we would expect New Yorkers who were parents at the time of the 9/11 attacks to have been at especially heightened risk for mental health problems. Parents are at increased risk for problems because the difficulties they face in addressing their own anxieties after a disaster are compounded by their empathy for their children's distress as well as their responsibility to help their children cope with the disaster. Phillips, Featherman, and Liu (2004) documented what they termed the evocative influence of children's stress symptoms on parents' own feelings of shaken security and threat, with adults exposed to children distressed by the events of 9/11 being twice as likely to feel threatened than adults who did not encounter distressed children. However, very little is known about how parents' mental health was affected by their children's exposure to the 9/11 attack, over and above their own exposure. We explore the possibility of reciprocal effects of parent and youth exposure on each others' mental health problems in this article.

Youth often turn to their parents for support in dealing with a traumatic event. In the aftermath of 9/11, 85% of youth residing just outside NYC used their parents as a source of support in the week after the 9/11 attacks, and 71% found parents' support to be beneficial (Gould, Munfakh, Kleinman, Lubell, & Provenzano, 2004). Although children's strategies for coping with a disaster or other stressful event have been shown to predict improved functioning (Compas, Worsham, & Ey, 1992; Vernberg, La Greca, Silverman, & Prinstein, 1996), and children do report receiving the most support from their parents and friends in the wake of disasters such as Hurricane Andrew or 9/11 (Phillips, Prince, & Schiebelhut, 2004; Prinstein, La Greca, Vernberg, & Silverman, 1996), there has been only limited research on the role parents play in helping children select coping strategies. This is despite the fact that official advice to parents in the wake of disasters specifically encourages parents to assist their children's coping with the disaster by talking with children and listening to their concerns as well as returning to predisaster routines as soon as possible (Federal Emergency Management Agency, 2004). Those studies of which we are aware have used child reports of parents' coping assistance (Prinstein et al., 1996; Vigil & Geary, 2008). In contrast, we examine parents' self-reports of their coping assistance, first as predicted by their own or their youth's exposure to a disaster, and then as predictors of youth mental health problems.

The effects of exposure to man-made disasters such as 9/11 are not restricted to mental health. Sociopolitical attitudes, such as prejudice toward immigrants and social mistrust, could also be affected. In particular, civil liberties groups were concerned that the nature of the attacks on NYC and Washington might evoke feelings of resentment of or prejudice toward immigrants and general mistrust of others. Such fears appear to have been unfounded; rather, the opposite appears to have occurred, with youth reporting more interest in politics and civic issues post-9/11 (Metz & Youniss, 2003). Putnam (2002) reported that young Americans' interest in public affairs increased by 27%, whereas trust in community leaders grew by 19%. Neither was there an observed increase in negative attitudes about immigrants as a result of the 9/11 attacks; even in the weeks immediately after 9/11, the majority (87%) of respondents in a national survey agreed that immigrants help make the United States more open to new cultures and ideas, and only 24% believed that immigrants contribute to increased crime in the United States (Traugott et al., 2002). In a survey 2 weeks after the attack, 61% of New Yorkers agreed that people are fair, 71% agreed that people are helpful, and 34% agreed that people are trustworthy; these attitudes remained largely unchanged 5 months after the attacks (Rasinski, Berktold, Smith, & Albertson, 2002). In this study, we examined whether and how the amount and type of individual and partner exposure to the events of 9/11 were associated with NYC youth's and mothers' sociopolitical attitudes several months after the attack.

The unpredictable nature of disasters such as terrorist attacks makes it especially difficult to judge their impact on individuals. Studies already in the field, preferably ones close to the disaster site, can provide a quick venue for disaster assessment by "piggybacking" disaster assessments onto preexisting studies (Gershoff & Aber, 2004). The results reported here draw from a study employing such a strategy. The study is the result of an amendment to a planned long-term follow-up of children in an evaluation of one of the largest school-based violence prevention programs in the country, the Resolving Conflict Creatively Program (RCCP).

The influence of RCCP on the social-cognitive, behavioral, and academic development of elementary school children has been reported elsewhere by Aber and colleagues (Aber, Brown, & Jones, 2003; Aber, Jones, Brown, Chaudry, & Samples, 1998; Brown, Roderick, Lantieri, & Aber, 2004). We include measures of exposure to the RCCP intervention as controls in these analyses.

Data collection began 4 months after 9/11 and ended 2 years later; interviews were on average 15 months after 9/11. This long time lapse between 9/11 and data collection is not ideal for detecting immediate effects. However, findings that individuals exposed to disasters tend to show impaired functioning for a full year after the event, and that for some individuals these effects last for years (Norris, Friedman, & Watson, 2002), suggest that our time window is appropriate for assessing lasting impacts of 9/11 exposure among individuals residing in NYC.

The first aim of this study was descriptive, namely to document the rates of exposure to the 9/11 terrorist attacks on the WTC among a sample of youth and their mothers in NYC. Unlike studies that have used a pre- and postattack design that assumes equal exposure to the attacks and their aftermath (e.g., Hendricks & Bornstein, 2007; Henry, Tolan, & Gorman-Smith, 2004; Metz & Youniss, 2003), we assessed three forms of actual exposure to the events of 9/11: individual direct exposure to the attacks and their immediate aftermath, family or friend direct exposure at the WTC site, and media exposure to coverage of the attack. To understand whether some youth and mothers were more likely than others to be exposed to the attack, we examined several demographic characteristics that have been associated with how well individuals cope with a disaster, namely gender, age, ethnicity, and socioeconomic status (see Norris, Friedman, Watson, Byrne, et al., 2002, and La Greca, Silverman, Vernberg, & Roberts, 2002, for reviews). We also were interested in whether youth and mothers reported similar or distinct rates of the three forms of exposure, given that youth tend to be more adversely affected by disasters than adults (see Norris, Friedman, Watson, Byrne, et al., 2002).

To determine the potential impact of 9/11 exposure on mental health, our second aim was to establish whether, controlling for demographic characteristics associated with exposure, self-reported direct, family and friend, and media exposure were associated with increases in youth's and mothers' PTSD and depression symptoms. We chose to focus on PTSD and depression because they are the two mental health problems most often observed after disasters (La Greca et al., 2002; Norris, Friedman, Watson, Byrne, et al., 2002). To examine potential bidirectional effects, we also tested whether partner exposure (i.e., mother exposure predicting youth symptoms, and youth exposure predicting mother symptoms) added to the likelihood that youth or their mothers reported symptoms of PTSD or depression.

Our third aim was to understand the role of parents' coping assistance in the face of such a disaster. We sought to determine whether the extent to which mothers assisted their adolescents in coping with the events of 9/11 was predicted by their own exposure or by their adolescents' exposure. We then examined whether mothers' coping assistance predicted lower rates of youth PTSD and depression symptomatology.

Finally, our fourth aim was to establish whether exposure to the events of 9/11 had any enduring association with youth's and mothers' reports of their families' and their personal sociopolitical attitudes. Specifically, we considered families' socialization around prejudice, social mistrust, and current events, as well as individuals' own attitudes about the level of trust in their communities and about immigrants' roles in their communities. As with the prediction of mental health, we also examined whether partner exposure predicted participants' sociopolitical attitudes over and above their own exposure.

Method

Participants

The sample for this study was drawn from a larger study of 908 youth who participated in a longitudinal follow-up of children in an evaluation of one of the largest school-based violence prevention programs in the country, the RCCP. For 498 of these youth, their primary caregiver was also interviewed. Of these 498 families, 31 were excluded because they were missing adolescent or caregiver exposure to the events of 9/11. Finally, only 40 of the primary caregivers were male; they were excluded from the analyses.

The final analysis sample consisted of 427 adolescents and their female caregivers residing in NYC. Because the vast majority of the female caregivers were mothers or stepmothers to the youth (94%), we will subsequently refer to them as "mothers." Adolescents ranged in age from 12 to 20 years ($M = 16.20$, $SD = 1.69$). The youth sample was 54% females and 47% Hispanic American, 35% African American, 14% European American, and 4% of another race (e.g., Asian, Native American). The majority of the adolescents reported the United States as their country of origin (87%), but nearly two thirds (64%) of them had at least one parent born outside the United States. In the follow-up, 31% of the participants were in 7th–9th grades, 54% were in 10th–12th grades, 5% were in a GED (general equivalency diploma) or vocational program, 6% were in college, 2% were working and not in school, and 2% were not working or not in school. Of the students in school, 26% reported that they worked part-time or full-time as well. Most adolescents indicated that they attended or had attended a public junior or senior high school (91%) in NYC.

The mothers averaged 42 years of age (*SD* = 7.11). Half of the mothers reported that they were married (50%). The race-ethnic breakdown of the mothers was roughly equal to that of the adolescents: 44% Hispanic American, 37% African American, 15% European American, and 4% of another race. Two thirds of the mothers worked (63%). The mothers reported a range of educational backgrounds: Ten percent had only elementary school education; 17% had attended, but not graduated from, high school; 28% were high school graduates; 26% had attended college for 1–3 years; and 19% were college graduates. The median education level among mothers was high school graduate. Fifty-one percent of the mothers were born outside the United States, in a total of 35 countries. Of the foreign countries of origin, the most frequently reported were the Dominican Republic (*n* = 50), Puerto Rico (*n* = 37), Jamaica (*n* = 23), and Haiti (*n* = 20).

Protocol

Families were recruited for the study through mailings and phone calls using contact information obtained from the New York City Department of Education. Recruitment letters were written in both English and Spanish. Once consent was obtained from parents and assent or consent was obtained from youth (depending on whether they were under or over 18), youth were interviewed in person by trained research assistants for 2–3 hr using a structured format. Youth entered their responses directly into a laptop computer. To minimize any intimidation adolescents might feel, the interviewers were diverse (over half of the interviewers were racial-ethnic minorities), primarily female, and entirely young adults. The interviews primarily took place at public spaces such as community libraries or local parks, and commercial establishments such as coffee shops, or, less frequently, adolescents' homes. The students were compensated $50 for their time.

Mother interviews followed a structured format that lasted approximately 1 hr. The majority of mother interviews were conducted by reading the complete questionnaire over the phone (55%). In 34% of the cases, the parent filled out a paper copy of the questionnaire in person with the interviewer, whereas 11% of the mothers filled out the paper copy on their own and mailed it to us. Both the written and oral versions of the parent interview were available in Spanish for mothers who preferred to read and speak Spanish; 21% of the mothers were either read the Spanish version of the questionnaire or completed a paper copy of the Spanish version. Mothers were compensated $25 for their time.

Measures

Exposure to the 9/11 Attacks on the WTC

Exposure to the terrorist attacks on NYC on September 11, 2001, and their aftermath were assessed through sections of an instrument created by Hoven et al. (2002, 2005) through collaboration with the New York City Department of Education and the Centers for Disease Control and Prevention. Three forms of exposure to the events of 9/11 were assessed: direct exposure, media exposure, and family and friend exposure. *Direct exposure* was a count of 13 potential experiences with the event (e.g., seeing the planes crash or the towers collapse, having to leave where they were for safety concerns, smelling the smoke after the event; see Table 1 for all items). To assess *family and friend exposure*, we asked respondents whether they knew someone who escaped the WTC unharmed, someone who was at the WTC on 9/11 and was physically hurt, or someone who was killed in the WTC. The family and friend exposure scale was a count across these three categories and thus ranged from 0 to 3. We asked youth and mothers to report the extent of their *media exposure* to the events of 9/11 by asking them how much they reported learning about the event from (a) TV; (b) newspapers, radio, or magazines; or (c) the Internet, on a scale of 0 (*none*), 1 (*some*), or 2 (*a lot*). Each respondent's media exposure score was an average of these three ratings.

Youth interviews were conducted an average of 443 days (*SD* = 176) after September 11, 2001, which is roughly equivalent to 15 months. Mothers

Table 1
Youth's and Mothers' Direct Exposure to the 9/11 Attack on the World Trade Center (WTC)

Type of direct exposure	Youth (%)	Mothers (%)
Smelled the smoke from the WTC buildings after the attack	51	64
Someone in family works near the WTC site	35	35
Had difficulty getting home that day	34	33
Had to leave the location where they were for safety reasons	29	18
Was in or near the cloud of smoke or dust caused by the attack	20	25
Parents have cut down on freedom to travel around the city since September 11 (youth)/ Feel travel around city is limited because of the attack (mothers)	18	53
Someone in family has lost job because of the attack	15	20
Saw the planes crash or the towers collapse with own eyes	10	12
Someone in family worked in rescue or relief services at the WTC site	12	19
Had to attend another school/workplace temporarily because it was closed due to the attack	1	6
Changed school/job permanently because of the attack	1	4
Was physically hurt during the attack	1	3
Had to move out of home because of the attack	< 1	2
Any one of the above	87	91

were interviewed on average 477 days (*SD* = 167) after 9/11, which is also roughly equivalent to 15 months. We included the intervals between 9/11 and the mothers' and youth's interviews as controls in all analyses.

Mothers' Coping Assistance to Youth

Mothers were asked to report the kinds of assistance they provided to their children in reaction to the 9/11 attacks using a version of the Children's Coping Assistance Checklist that we adapted to be a parent-report measure (Prinstein et al., 1996). Three types of coping assistance were assessed: emotional processing, roles and routines, and distraction. *Emotional processing* included items such as, "I talked with my child about things she or he remembered most about the attack." The *roles and routines* subscale included items such as, "I did things with my child that made him or her feel like things were back to normal since the attack." The *distraction* coping assistance subscale included items such as, "I did things with my child to help him or her forget about the attack." In this study, the coping assistance subscales had strong internal consistency: emotional processing, $\alpha = .90$; roles and routines, $\alpha = .84$; distraction, $\alpha = .90$. Each subscale ranged from 1 to 4 (emotional processing: $M = 2.36$, $SD = 0.71$; roles and routines: $M = 2.66$, $SD = 0.84$; distraction: $M = 2.25$, $SD = 0.95$).

Youth's Mental Health

Youth's *PTSD symptoms* and *depression symptoms* were both assessed using the Computer Diagnostic Interview Schedule for Children–IV (C-DISC Development Group, 2000). The C-DISC is a highly structured interview designed to assess *DSM–IV* psychiatric disorders and symptoms in children and adolescents aged 9–17 years through self-report. (Although a young adult version for 18- to 25-year-olds was under development and not available for use in this study, the DISC has been used successfully with an 18- to 24-year-old population; see Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000.) The adolescents were asked if they had experienced symptoms of major depression or PTSD during the past year. Previous research has found that the C-DISC–IV is answered more consistently than any other psychiatric diagnostic interview that has been prepared for either children or adults and has established reliability (C-DISC Development Group, 2000; Shaffer et al., 2000). Although clinical cutoffs applied by the DISC algorithm revealed that 4% of youth reached the level of a clinical diagnosis of PTSD symptoms in the last year and that 12% reached clinical levels of major depression disorder, for these analyses we used continuous counts of symptoms to capture the full range of symptomatology. It is also important to note that the PTSD symptoms reported by adolescents could be about any traumatic life event, not necessarily the events of September 11; only 10 of the 427 youth reported September 11 as their major traumatic life event.

Mothers' Mental Health

Mothers' *PTSD symptoms* were assessed using the PTSD subscale of the DISC Predictive Scales (DPS; Lucas et al., 2001). The DPS was created by the developers of the full interview to maximize specificity and sensitivity and to be predictive of full DISC diagnoses (Lucas et al., 2001). The DPS PTSD subscale is an eight-item scale; scores range from 0 to 1. For this sample of mothers, the DPS PTSD scale had acceptable internal consistency, $\alpha = .74$ ($M = 0.34$, $SD = 0.25$). The developers of the DPS suggest that the endorsement of five or more symptoms indicates a probably clinical level of the disorder (Lucas et al., 2001); applying this criterion, 20% of the mothers in our sample had probable clinical levels of PTSD. However, for our analyses, we used the symptom count as a continuous score to best capture the full variability of PTSD symptoms among mothers in our sample.

Mothers' *depression symptoms* were identified using the Center for Epidemiological Studies Depression Scale (CES–D; Radloff, 1977). Designed to assess depressive symptoms in normal populations, this widely used scale asks respondents to rate the frequency with which 20 states or behaviors related to depression occurred during the past week (e.g., "I felt sad," "I felt that everything I did was an effort," "I enjoyed life"). The CES–D scale had excellent internal consistency with this sample ($\alpha = .90$; $M = 12.65$, $SD = 10.87$). Radloff (1977) identified 16 or more symptoms as a cutoff for potential clinical levels of depression. Mothers in our sample had CES–D scores of as high as 57 (of a possible 60), and 34% of the mothers reported elevated depression symptoms at or above the cutoff score of 16. As with youth's mental health symptoms and mothers' PTSD symptoms, however, we used the count of depressive symptoms as a continuous measure in our analyses.

Family and Personal Sociopolitical Attitudes

Both youth's and mothers' perceptions of the mothers' socialization around certain sociopolitical issues and of their own sociopolitical attitudes were assessed using the Intergroup Understanding or Bias Questionnaire (Flanagan, Gill, & Gallay, 1998; Flanagan, Ingram, Gallay, & Gallay, 1997). The questionnaire was written for adolescents and young adults; we created a companion version for parents. For this study, we used three subscales from this measure regarding sociopolitical socialization: family lessons about prejudice, family discussions of current events, and family lessons about social mistrust. We also asked youth and mothers to complete subscales tapping two aspects of their sociopolitical attitudes, namely social integration and prejudice toward immigrants. Responses to all items were along a scale from 1 (*strongly disagree*) to 5 (*strongly agree*).

Family lessons about prejudice. This subscale included five items that asked respondents how much they agreed with statements such as, "My parents have taught me [I have taught my children] it is wrong to judge people before you get to know them" and "My parents have told me [I have told my children] there might be times when people will be prejudiced against me [them]." This subscale showed strong internal consistency for the youth ($\alpha = .78$; $M = 4.07$, $SD = 0.74$) and adequate internal consistency for the mothers ($\alpha = .69$; $M = 4.38$, $SD = 0.54$) in this sample.

Family lessons about social mistrust. This subscale consisted of four items, including, "My parents have warned me [I have warned my children] that people sometimes take advantage of you," and "My parents have warned me [I have warned my children] you can't always trust people." This subscale had strong internal consistency for the youth ($\alpha = .83$; $M = 4.21$, $SD = 0.77$) and adequate consistency for the mothers ($\alpha = .65$; $M = 4.33$, $SD = 0.52$) in this sample.

Family discussions of current events. Comprising six items, this subscale includes items such as, "In my house we have many discussions about current events and politics" and "I tell my parents [my children] my opinions about events in the news." This subscale showed strong internal consistency for the youth ($\alpha = .83$; $M = 3.36$, $SD = 0.81$) and adequate internal consistency for the mothers ($\alpha = .71$; $M = 3.77$, $SD = 0.60$) in this sample.

Social integration. The six items in this subscale include statements such as, "Most people in our community try to make this a good place to live" and "If someone in our community has a problem, they can usually count on others to help them out." This subscale showed equally strong internal consistency for the youth ($\alpha = .84$; $M = 3.00$, $SD = 0.81$) and the mothers ($\alpha = .84$; $M = 3.13$, $SD = 0.76$).

Prejudice toward immigrants. For this subscale, respondents indicated their agreement with nine statements such as, "If they want to be accepted, immigrants should learn our customs and language" and "The children of immigrants should have the right to a good education in our country" (reversed). This subscale also showed strong internal consistency for both the youth ($\alpha = .78$; $M = 2.25$, $SD = 0.61$) and the mothers ($\alpha = .75$; $M = 3.65$, $SD = 0.56$) in this sample.

Components of RCCP Intervention

Experience with the intervention in middle childhood was operationalized using data on two primary RCCP components. *Classroom instruction* in RCCP is composed of the total number of lessons given by trained teachers to children in their classrooms across the 2 years of the evaluation (range = 0–10, *M* = 2.36, *SD* = 2.53). *Teacher training and coaching* is a count of the number of contacts a teacher had with the RCCP and consists of training sessions attended, one-on-one meetings with an RCCP staff developer, and classroom visits by the staff developer (range = 0–8, *M* = 2.10, *SD* = 2.02). (Please see Aber et al., 1998, 2003, for more in-depth discussions of these variables.) As stated earlier, we included these two aspects of the RCCP intervention in the analyses as controls only.

Results

Youth and Mother Exposure to the 9/11 Terrorist Attacks on the WTC

The vast majority of both youth (87%) and their mothers (91%) reported one or more forms of direct exposure to the 9/11 attacks on the WTC and their aftermath (see Table 1). Youth reported an average of 3.27 forms of direct exposure (*SD* = 1.85), with a low of 0 and a high of 9 forms of direct exposure. Mothers reported more forms of direct exposure, averaging 4.22 (*SD* = 2.29) and ranging from 0 to 12 forms of direct exposure. One in 10 youth and 1 in 8 mothers reported having seen the planes crash into the Twin Towers or the towers collapse with their own eyes. Thankfully, few reported having been physically hurt themselves in the attacks (youth: 1%; mothers: 3%), but 1 in 5 youth and 1 in 4 mothers reported being in or near the cloud of smoke or dust that resulted from the towers' collapse. One half of youth and nearly two thirds of mothers reported smelling the smoke from the WTC site after the attack. Equivalent numbers of youth and mothers reported having difficulty getting home that day (34% and 33%), although more youth reported that they had to leave the location where they were for safety reasons because of the attacks (youth: 29%; mothers: 18%). Half of the mothers felt that their travel around the city was limited because of the attacks (53%); we did not ask this specific question of the youth, but when we asked youth if they felt their parents had restricted their travel around the city because of the attack, only 18% said "yes." Youth and mothers were equally likely to say that someone in their family works near the WTC site (35%), although mothers were slightly more likely to report that someone in the family lost their job because of the attacks (20% vs. 15%) or that someone in the family worked in rescue or relief services at the WTC site (19% vs. 12%). Very few respondents (6% or less) reported that they had to change their school or their workplace, either temporarily or permanently, or that they had to move out of their home because of the attack.

Mothers were more likely than youth to report each form of family and friend exposure to the 9/11 attacks (see Table 2). Slightly less than half of all youth and two thirds of mothers reported one or more forms of family and friend exposure to 9/11; the average for youth was less than one form of family and friend exposure (*M* = 0.61, *SD* = 0.74), whereas for mothers the average was one form of family and friend exposure (*M* = 1.02, *SD* = 0.94). Mothers were twice as likely as youth to disclose that they knew someone who was killed in the attacks on the WTC (39% vs. 21%).

Regarding media exposure to 9/11, nearly all youth and all mothers reported learning about the attacks by watching TV (96% of youth and 98% of mothers; see Table 3). The percentages of youth and mothers who reported learning about the attacks from radio, newspapers, or magazines were also roughly equal at 93% and 91%, respectively. Youth were more likely to have used the Internet to learn about the attacks (38%) than mothers (25%). When their ratings for each of these forms of media exposure were combined into one subscale, youth's and mothers' average media exposures were strikingly similar: youth media exposure, *M* = 1.20, *SD* = 0.44; mothers' media exposure, *M* = 1.29, *SD* = 0.40.

Table 2
Youth's and Mothers' Family and Friend Exposure to the 9/11 Attack on the World Trade Center (WTC)

	Youth (%)	Mothers (%)
Knew someone who was in the WTC on the day of the attack but escaped without being hurt	34	47
Knew someone who was physically hurt in the WTC attack but not killed	7	16
Knew someone who was killed in the WTC	21	39
Any one of the above	47	64

A lot	12	8
Some	27	17
None	62	75

We next examined whether certain groups of individuals were more vulnerable to exposure to the terrorist attacks than others. Table 4 contains the results of six separate regressions predicting youth and then mother direct, family and friend, and media exposure. Demographic characteristics largely did not predict exposure, with only two of the six models significant. Even the significant models, predicting youth's and then mothers' family and friend exposure, did only a modest job predicting the variance in exposure (8% and 10%, respectively). In the model predicting youth family and friend exposure, girls reported more, and African Americans and Hispanics Americans less, exposure. African Americans and Hispanic American mothers as well as mothers of another race or ethnicity also reported less family and friend exposure than European American mothers. Mothers with higher levels of education reported more family and friend exposure. Notably, the time lapse between 9/11 and the date of the youth or mother interview was not significantly associated with the amount of exposure reported by participants.

Exposure to 9/11 and Mental Health

To determine the impact of exposure to 9/11 on youth's and mothers' PTSD and depression symptoms, we conducted two regressions for each outcome. We first regressed the mental health outcome on youth and mother demographic characteristics and respondents' own 9/11 exposures to the model (e.g., youth exposure predicting youth PTSD symptoms), reported as Model A in Table 5. We then ran

Table 4
Demographic Predictors of Youth and Mother Exposure to 9/11

a second set of models, adding partner's exposures as predictors of mental health (e.g., mother exposure predicting youth PTSD symptoms). We report the results of these models as Model B in Table 5. By running the analyses in these two stages, we are able to isolate the impacts of own and partner exposure on PTSD and depression symptoms from each other while controlling for demographic characteristics.

Turning first to the prediction of youth mental health, we found that although youth's own direct exposure to 9/11 contributed significantly to the prediction of their self-reported depression symptoms, exposure did not predict youth's PTSD symptoms. Each of the minority race-ethnic groups reported more PTSD symptoms compared to European American youth, whereas youth who are second-generation immigrants reported fewer PTSD symptoms. Girls reported more, and first-generation immigrant youth fewer, depression symptoms. In neither of the two regressions for Model B was the F_{Δ} statistic significant; thus, none of mothers' exposures to 9/11 predicted youth PTSD or depression symptoms.

Mothers' own direct exposure to 9/11 did predict more of their own PTSD symptoms, over and above the contribution of demographic characteristics, $F(17, 321) = 5.04$, $p < .001$. Mothers' family and friend exposure and media exposure did not predict their own PTSD symptoms, and none of the forms of mothers' exposure to 9/11 predicted their depression symptoms. Mothers with higher levels of education reported fewer PTSD and depression symptoms, and employed mothers reported fewer depression symptoms; no other demographic characteristics predicted symptoms. The addition of youth exposure to the regressions did not improve any of the models significantly. Youth media exposure did predict mothers' PTSD symptoms (the more media exposure reported by youth, the fewer PTSD symptoms reported by mothers), although youth media exposure did not significantly improve the prediction of mothers' PTSD symptoms over and above demographic characteristics and mothers' own exposure.

Mothers' Coping Assistance as a Function of Exposure to 9/11

To determine whether mothers' coping assistance was in response to exposure to 9/11, we regressed each of the three forms of coping assistance first on mothers' exposure and then on youth's exposure. We followed a two-regression sequence similar to that used in the prediction of mental health outcomes, again to isolate the unique impacts of mothers' and youth's exposure to 9/11 on mothers' coping assistance. The results from these sets of regressions are presented in Table 6. Older mothers reported using emotional processing and roles and routines coping assistance less than younger mothers, whereas Hispanic American mothers reported using more distraction coping than European American mothers. Mother education was associated with less use of distraction coping, whereas mother employment was associated with more roles and routines coping.

The extent to which mothers engaged in emotional processing coping was significantly predicted from their own direct exposure to 9/11; the more direct exposure mothers experienced, the more they engaged in emotional processing coping with their adolescents ($\beta = .23$, $p < .001$). However, the extent to which mothers used roles and routines or distraction as methods of helping their children cope with the events of 9/11 was not predicted by the extent of their own exposure. Contrary to our prediction, mothers' coping assistance was not a function of the extent of youth's direct, family and friend, or media exposure to the events of 9/11; in other words, mothers did not engage in certain forms of coping assistance depending on the type of exposure their children experienced.

Mothers' Coping Assistance and Youth Mental Health

We examined whether mothers' coping assistance was associated with youth mental health by regressing youth PTSD symptoms and depression symptoms first on youth exposure to 9/11 and then on the three forms of mothers' coping. The pattern of significant demographic predictors was the same as that presented in Table 5. We again used two regressions to allow us to consider the possibility that mothers' coping assistance might function as mediators of the impact of youth exposure on their mental health. However, after the impact of youth's exposure to 9/11 on their mental health was controlled in Model A, none of the forms of mothers' coping assistance predicted youth mental health in either Model B (see Table 7).

Exposure to 9/11 and Youth Reports of Family and Personal Sociopolitical Attitudes

Youth's and mothers' exposure to 9/11 were used as predictors of youth reports of three

aspects of family sociopolitical attitudes, namely family lessons about prejudice, family discussions about current events, and family discussions about social mistrust. Girls, African Americans, and Hispanic Americans were most likely to report their parents taught them about prejudice and about needing to mistrust others. Youth whose parents are immigrants report more trust in their local communities, whereas both African American and Hispanic American youth reported less trust. Youth whose mothers were married or working reported less prejudice toward immigrants. Interestingly, youth's prejudice toward immigrants was higher the longer the gap between 9/11 and their interviews.

The more youth reported media exposure to 9/11, the more likely they were to agree that their family discussed circumstances in which they might personally encounter prejudice, as well as the extent to which they should be vigilant about

and distrustful of other people (see Table 8). Youth media exposure was also associated with more family discussions of current events. Mothers' exposure to 9/11 was not predictive of any of the youth-reported measures of family sociopolitical attitudes. Regarding youth's self-reported sociopolitical attitudes, youth's media exposure significantly predicted youth's trust in the local community. The only sociopolitical attitude affected by youth's direct exposure to 9/11 was their prejudice toward immigrants, although it did not account for a significant improvement in the R^2. Contrary to expectation, more exposed youth reported less, not more, prejudice toward immigrants.

Exposure to 9/11 and Mother Reports of Family and Personal Sociopolitical Attitudes

Similar to the models predicting youth reports, mothers' reports of the extent of their own socialization of their adolescents around issues of prejudice, social mistrust, and current events were predicted significantly by their own media exposure to 9/11 (see Table 9). In addition, mothers' family and friend exposure predicted a greater extent of mother-reported family lessons about prejudice, whereas the more mothers reported direct exposure to 9/11, the less likely they were to discuss issues of social mistrust with their adolescents. Youth exposure did not significantly

improve the prediction when added in the second models.

In the models predicting mothers' own sociopolitical attitudes, neither mothers' own nor youth's exposure to 9/11 predicted mothers' trust in the local community. Mothers' prejudice toward immigrants was predicted by their media exposure, with more exposure associated with less prejudice toward immigrants. Youth exposure to 9/11 did not predict mothers' self-reported trust in the local community or mothers' self-reported prejudice toward immigrants.

African American and Hispanic American mothers reported higher levels of talking with their children about social mistrust and less likely to have trust in their local community. Mothers who are immigrants or married to an immigrant report more trust in their local communities and, somewhat surprisingly, more prejudice toward fellow immigrants. Older mothers report more trust in their communities, married mothers report fewer family lessons about social mistrust, and educated mothers report more family discussions about current events.

Discussion

The 9/11 attacks live on in the memories of many Americans and most New Yorkers. Our main conclusion from this study is thus a surprising one—namely that variations in exposure to the events of 9/11 had very modest associations with the longer term mental health of New York youth and their mothers. We also found that variation in exposure to the events of 9/11 was associated to a small degree with both mothers' coping assistance and youth's and mothers' sociopolitical attitudes. We found little evidence of reciprocal influences of mothers' or youth's exposure on each others' mental health and sociopolitical attitudes.

Exposure to 9/11 and Parent and Youth Mental Health

Although other studies have found that media exposure alone to the 9/11 attacks induced PTSD symptoms in children geographically distant from the sites of the attacks (Otto et al., 2007), we did not replicate this finding with our NYC sample, instead determining that only direct exposure was associated with youth's and mothers' mental health. It may be that direct exposure to the attacks overshadowed the impacts of media exposure among individuals so proximal to the attack site. The physical reminders of the attack, including the smoke rising from what was left of the towers, the restricted access to Lower Manhattan, the rerouted subways, and the pictures of missing victims of the attacks posted around the city in vain by family members, were present for days and weeks afterward, prolonging exposure to the attacks among New Yorkers. It may also be that families living so close to the site of the attacks felt less reason than Americans living elsewhere to turn to the media to learn about the attack, as they need only go to any street corner, subway car, diner, or office lunchroom to hear the latest information on victim counts, conspiracy theories, and warnings of future attacks.

Despite nearly universal direct exposure to the 9/11 attacks, very little of the variance in the mental health symptoms of youth and parents in our study was explained by 9/11 exposure. Even for the two models in which exposure to 9/11 significantly predicted symptomatology, exposure accounted for only 2% of the variance in youth depression symptoms and 7% of the variance in mothers' PTSD symptoms. The lack of association between 9/11 exposure and mental health symptoms may be a function of the length of time between 9/11 and the interviews (on average 15 months for both youth and their mothers). Although we controlled for the time lapse between 9/11 and each interview, we identified few enduring associations of 9/11 exposure with youth's and mothers' mental health. It is still quite possible, if not likely, that there were more immediate effects of 9/11 exposure on the mental health of our participants, but our results suggest that any such impacts on PTSD and depression symptoms have largely receded with the passage of time.

Given the nontrivial rates of PTSD (youth: 4%; mothers: 20%) and depression (youth: 12%; mothers: 34%) symptoms in this sample of youth and their mothers living in NYC, it is clear that something other than the trauma of the 9/11 attacks is responsible for these elevated levels of problematic mental health symptoms. In our previous empirical paper from this study (Aber, Gershoff, Ware, & Kotler, 2004), we explored community violence exposure as a potential predictor and found that exposure to community violence as a victim or witness significantly predicted PTSD and depression symptoms, with near zero associations for 9/11 exposure dwarfed by the very large effects of violence victimization. We concluded then that the effects of traumatic events such as disasters and terrorist attacks need to be understood in the context of youth's everyday lives. Similarly, parents' PTSD and depression symptoms may be predicted more by daily exposures to stress or violence in their homes and communities. Unfortunately, we did not have measures of mothers' individual violence exposure in this study and so could not test this alternative hypothesis; such a question is ripe for future research. We encourage future researchers of the impacts of disasters to include measures of "everyday" stress and violence to put the impacts of disasters in context.

Other studies of 9/11 have found similarly modest associations of 9/11 exposure with child and youth mental health. One longitudinal study of children in NYC found that parents reported fewer child behavior problems 4 months after the attack, but by 6 months later behavior problems had returned to pre-9/11 levels (Stuber et al., 2005). Similarly, a study of high school students in Boston found that while political interest and civic participation increased slightly right after 9/11, they returned to pre-9/11 levels by 9 months after the attacks (Metz & Youniss, 2003). A study of 9- to 13-year-olds similarly found that neither knowing someone directly affected by the attacks nor having moderate media exposure to the 9/11 attacks predicted children's PTSD symptoms 7 months after 9/11 (Lengua, Long, & Meltzoff, 2006). In that study, preattack stress load (e.g., moving, serious illness/injury, death of a loved one) and the extent of children's 9/11-specific threat appraisal and avoidant coping were much stronger predictors of PTSD symptoms. Among fourth graders living in inner-city Chicago at the time of the 9/11 attack, those assessed post-9/11 did not have higher levels of depression symptoms than the children assessed pre-9/11 (Henry et al., 2004).

The good news of our null findings is that even among a sample of families with extensive direct exposure to the 9/11 terrorist attacks and its aftermath, there were few lasting associations of this exposure with mental health on average 1 year later. We may be tempted to conclude that youth and their mothers are "resilient" to the impacts of 9/11. However, resilience is a dynamic construct that involves positive adaptation after an experience of adversity (Luthar, Cicchetti, & Becker, 2000). To determine whether our participants are in fact doing as well as they were before 9/11, we would need pre- and postmeasures of functioning. Without preevent measures, we are only able to predict post-9/11 levels of functioning and not change or adaptation of functioning after 9/11. We further argue that any conclusion about resilience in our sample is belied by the fact that the mothers and youth in our sample reported high levels of symptomatology over 1 year after the 9/11 attack. If 9/11 is not the cause of these mental health problems, what is? We suggest that greater attention needs to be paid to everyday stress and trauma in the lives of inner-city families.

Exposure to 9/11 and Parent Coping Assistance

Mothers of youth in New York did report small differences in their modes of helping their children cope with 9/11 depending on their own exposure. Specifically, mothers' higher direct exposure was associated with higher levels of coping focused on emotions. Yet in contrast to the literature that describes an important role for parents' coping styles in helping children and youth adjust after a disaster (Compas et al., 1992; Vernberg et al., 1996), we found that mothers' self-reported coping assistance to their adolescents was not associated with adolescents' PTSD and depression symptoms. Ours is not the only study to not find positive outcomes associated with parental coping; in a study of adolescents whose families were displaced by Hurricane Katrina, only one of five forms of parental coping was associated with youth mental health, namely the extent to which parents sought professional help for their adolescents, and the association was with higher distress and depression scores (Vigil & Geary, 2008).

Exposure to 9/11 and Sociopolitical Attitudes

In contrast to the meager associations between exposure to the events of 9/11 and mental health, there were more and stronger associations between youth's and mothers' exposure and their family and personal sociopolitical attitudes. Of the three types of youth's exposure, media exposure had the clearest connection to youth attitudes, being associated with four of the five sociopolitical constructs measured, namely family lessons about prejudice, mistrust, and current events as well as youth's trust in their local communities. Youth with more media exposure had families more actively engaged in a political socialization process after the events of 9/11. Youth family and friend exposure and direct exposure were, in large part, not associated with families' sociopolitical socialization or with youth's sociopolitical attitudes.

A notable exception to this pattern was the association between youth direct exposure and less prejudice toward immigrants. This finding suggests that public concern that a consequence of 9/11 would be an increase in xenophobia was misplaced. Interestingly, youth's prejudice toward immigrants was not predicted by their own or their parents' immigrant status; given that fully 64% of the youth had at least one parent who was born outside the United States and thus are themselves second-generation immigrant youth, it may be that generational status does not differentiate among these youth. It is also important to note that we asked about prejudice toward immigrants in general, not toward any specific immigrant groups. If we had asked specifically about prejudice toward Muslims or Arabs, the groups most associated with the 9/11 terrorist attackers, we may very well have found that exposure to 9/11 predicted more prejudice toward these groups.

Mothers' reports of family and personal sociopolitical attitudes were associated with their own exposure. As with their adolescents, mothers' media exposure was most strongly and consistently predictive of the extent to which mothers report they socialize their children regarding the issues of prejudice, social mistrust, and current events. For mothers, media exposure predicted less prejudice toward immigrants, and direct exposure predicted less socialization around social mistrust.

Taken together, this pattern of findings suggests that, while the events of 9/11 were associated with limited enduring associations with the mental health of youth and their mothers, 9/11 exposure did predict mothers' socialization of and youth's development of sociopolitical attitudes. It is important to note, however, that any significant associations with 9/11 exposure occurred largely within persons (in the form of individual effects) rather than across persons (as reciprocal effects).

Limitations

Several aspects of the study limit the strength of our conclusions. First, all of the data were collected via self-reports and so are susceptible to reporter bias. For instance, if more sociopolitically engaged mothers and adolescents are more media attentive, the association between media exposure and sociopolitical attitudes could be epiphenomenal. Second, while the events of 9/11 constitute a truly uncontrollable, exogenous shock, recalling exposure is not purely exogenous. The associations we report are vulnerable to selection effects. Although we would have preferred to model selection into our models, data limitations prevented us from doing so. However, by reporting the extent to which individual characteristics predicted "selection" into 9/11 exposure and by including these characteristics in our models, we have accounted for selection effects.

There are also many limitations characteristic of disaster studies, particularly inadequate predisaster "baseline" data (see Aber & Gershoff, 2004; Gershoff & Aber, 2004, for more comprehensive review of such limitations), which this study was unable to transcend. As noted earlier, context matters in understanding the effect of systemic violence and man-made disaster on child and parent development (Aber et al., 2004). This was not a study of the distant trauma of 9/11 but rather was a study of parents and youth who were in NYC on 9/11 and thus in close proximity to the attacks on the WTC. Nor was this a study of a demographically representative sample of NYC children (see Hoven et al., 2005, for such a study). Rather, this was a study of primarily Hispanic American and African American families from low-income communities. These contextual factors limit our ability to generalize these findings to broader populations. But they also help generate ideas about how contextual factors may moderate some of the influences we investigated in this study. To help inform not only developmental theory and research but also program and policy initiatives related to children and parents in disasters or other emergencies, the field needs to develop a more complete and unifying theoretical frame for the integration of such studies as Norris and colleagues (Norris, Friedman, Watson, Byrne, et al., 2002) have begun to do.

Conclusion

We have used rich data on three forms of exposure to the 9/11 terrorist attacks to examine whether such exposure had long-term impacts on youth and their families living, working, and going to school in relatively close proximity to the site of the WTC attacks. Rather than finding evidence of enduring impairment following from the attacks on 9/11, we have found a silver lining. Exposure to the 9/11 attacks appears to have prompted these families to have more discussions about serious social and political issues, discussions that we hope will lead to a more informed and civically minded generation of young adults.

The Effects of the 1999 Turkish Earthquake on Young Children: Analyzing Traumatized Children's Completion of Short Stories

Elif Celebi Oncu
Oregon State University

Aysegul Metindogan Wise
Bogazici University

The purpose of this exploratory study was to determine whether projective techniques could identify long-term consequences among children stemming from exposure to a traumatic event. The first group of children ($n = 53$; 26 female, 27 male) experienced 2 major earthquakes at age 7, 3 months apart, in Turkey, while a similarly matched control group ($n = 50$; 25 female, 25 male) did not. Both groups of children (current age: 9) completed a series of short stories related to disastrous events. Results indicated that the traumatized group evinced a range of trauma-related symptoms 2 years after experiencing the earthquakes.

On August 17, a 7.4-magnitude earthquake occurred in Golcuk, Kocaeli, with effects felt in the neighboring provinces of Yalova, Istanbul, Sakarya, Bursa, Bolu, and Eskisehir. Soon after the Golcuk earthquake, on November 12, a second earthquake hit the neighboring province of Duzce with a magnitude of 7.2. The high magnitudes of the earthquakes along with the poor infrastructure in the affected areas resulted in tremendous losses. According to the United Nations Childrens Fund (UNICEF; 2001), 18,000 people died, 44,000 were injured, and more than 600,000 people were left homeless out of a total of 2 million people. The effects of the earthquake were exacerbated when the roads and railways became unusable, water and sewage were cut, and the electricity grid no longer functioned. According to the Earthquake Research Department of the General Directorate of Disaster Affairs, the financial damage caused by natural disasters, including earthquakes, in Turkey within the last 10 years is US$20 billion (http://www.deprem.gov.tr/dogalafet.htm). It is estimated that US$1.5 billion of that loss is due to the damage that was caused to the infrastructure of the earthquake-hit areas (UNICEF, 2001).

Because the North Anatolian fault line stretches across Turkey, geologists expect there will be an even bigger earthquake (referred to as the ''Marmara earthquake'') to occur in the northwestern side of the country within the next 30 years, including both the previous earthquake areas and Istanbul, a city of 15 million people. Thus, especially recently, researchers have been focusing on identifying the effects of these earthquakes and the ways in which adults and children deal with them (Basoglu, Salcioglu, & Livanou, 2002; Bulut, Bulut, & Tayli, 2005; Kilic et al., 2006). Kilic et al. (2006) focused on adults and found that relocation after the earthquake was associated with depression and posttraumatic stress disorder (PTSD). On the other hand, Bulut et al. (2005) found that children experienced PTSD even though there was no relocation. It appears that adults and children may be affected by the disaster differently and it is important to further investigate the delayed effects of earthquake in order to be prepared for a possible future disaster and to deal with its consequences.

The Emotional Consequences of Trauma or Disaster

Although traumatic events differ in nature, based on whether they are human-made or natural, the effects of traumatic events show some similarities in the effects they produce. One of the reasons natural disasters affect children more dramatically than many human-made trauma, such as abuse or neglect, is that natural disasters such as earthquakes occur fast and unexpectedly (Durkin, Khan, Davidson, Zaman, & Stein, 1993; Monahon, 1997). Moreover, these unexpected events affect people's moods directly, especially children's, and can cause

trauma (Azarian & Skriptchenko-Gregorian, 1998; Durkin et al., 1993; Jones, Frary, Cunningham, Weddle, & Kaiser, 2001; Mercuri & Angelique, 2004; Monahon, 1997; Yule, 2001). The extent and severity with which natural disasters affect children depend on numerous factors, including the child's age, gender (Gray Deering, 2000; Monahon, 1997; Vizek-Vidovic, Kuterovac-Jagodic, & Arambasic, 2000), developmental level (Falasca & Caulfield, 1999), education, and personality. Previous studies showed that boys have been found to react with more aggression and externalizing problem behaviors whereas girls are reported to respond to traumatic events with internalizing problem behaviors such as depression (Monahon, 1997; Vizek-Vidovic et al., 2000; Winje & Ulvik, 1998).

Some studies investigating children's reactions to disasters have demonstrated that the degree of emotional reaction to trauma is related to the proximity of the disaster (Jones et al., 2001; Najarian, Goenjian, Pelcovitz, Mandel, & Najarian, 1996). However, other studies indicate that it is not proximity to the disaster but rather the subjective experience of the disaster that predicts PTSD (Gokben Hizli, Taskintuna, Isikli, Kilic & Zileli, 2008). Gokben Hizli et al. (2008) found that depressive symptoms of adolescents endured 4 years after the earthquake in Turkey as a function of subjective negative perceptions of the disaster. Neria, Nandi, and Galea (2008) conducted a systematic review of studies that focused on investigating posttraumatic stress after experiencing a disaster between 1980 and 2007. Of 284 studies, there were three different identified categories of disasters: human-made, technological, and natural disasters. Neria et al. (2008) argued that although there seems to be some differences in the outcome, the effects of natural disasters were similar to the effects of human-made and technological disasters. For example, it appears that PTSD is less common after a natural disaster compared to the other types of disasters. However, the authors argue, when an earthquake hits, it is a larger scale disaster than human-made and technological disasters; thus, studies include victims who are in the center and experience the disaster directly and those who are further away from the center and experienced it indirectly. As a consequence, it seems that whether a negative event is experienced as a disaster is related to how many people it affects and how serious the consequences of the negative event are rather than whether the original cause was human-made, technological, or natural (Neria et al., 2008). In a study conducted by Mercuri and Angelique (2004), the PTSD levels of children were examined among natural, technological, and nontechnological disasters. It was found that children had exhibited increased levels of PTSD when they witnessed scenes of destruction and/or experienced life threat regardless of the type of disaster. And they found in the studies that it is important to ask children directly about their postdisaster reactions because none of the studies they had examined, in which parent measures were used, reported any significant PTSD in children.

Previous disaster research shows that traumatized children displayed problems of emotional and behavioral disturbances such as flaring tempers phobias, anxiety, sleep and eating disorders, and enuresis (Azarian & Skriptchenko-Gregorian, 1998; Durkin et al., 1993; Goenjian et al., 1995; Gurwitch, Silovsky, Shultz, Kees, & Burlingame, 2002; McAdam Crisp, 2006; Shen & Sink, 2002; Yule, 2001). Although most children are affected by the consequences of natural disasters, effects of disasters and perceptions of traumatizing events can vary from child to child. Factors such as age, gender, education, and personality can determine the degree of the trauma experienced by children (Giannopoulou et al., 2006). Boys have been found to react with more aggression and externalizing problem behaviors whereas girls are reported to respond to traumatic events with more internalizing problem behaviors such as depression (Giannopoulou et al., 2006; Monahon, 1997; Vizek-Vidovic et al., 2000; Winje & Ulvik, 1998).

Children's reactions to a disaster vary in quality depending on whether they are preschoolers, school-aged children, or adolescents (Vizek-Vidovic et al., 2000). Gray Deering (2000) suggested that preschool children had difficulty understanding disasters. In addition, Gray Deering (2000) argued that preschool children are egocentric in their thinking and as a result they can feel guilty and blame themselves for what happened. Young children's reactions to disaster can also include antisocial behaviors, aggression, and regression (Gray Deering, 2000; Yule, 2001). School-aged children have shown aggression, withdrawal, feelings of anxiety, fear, helplessness, grief, and worries about safety of self and others, and worries about reoccurrence of the traumatic event (Durkin et al., 1993; Pynoos, Goenjian, & Steinberg, 1998; Shaw, Applagate, & Schorr, 1996; Shen & Sink, 2002). Thus, children differ in their reactions to trauma and in their behaviors after the trauma is experienced based on their age and their level of understanding of the negative event (Giannopoulou et al., 2006; Mercuri & Angelique, 2004; Wolmer, Laor, Dedeoglu, & Yazgan, 2005).

Disasters are frequently associated with both short- and long-term physical and psychological problems (Neria et al., 2008; Pynoos et al., 1998). Some of the immediate problems children face includes having to live in difficult and stressful environments and facing the facts of the reality of the catastrophe. Researchers have shown that PTSD and depression are sustained for many years after disasters or traumatic events (Basoglu et al., 2002; Chemtob, Nakashima, & Carlson, 2002; Najarian et al., 1996; Shaw et al., 1996; Shen & Sink, 2002; Winje & Ulvik, 1998; Wolmer et al., 2005).

Previous postdisaster research has demonstrated that the effects of traumatizing events endure for a long time (Chemtob et al., 2002; Winje & Ulvik, 1998; Wolmer et al., 2005). A study of childhood PTSD 6 months after Hurricane Floyd revealed that children clearly demonstrated the devastating effects of a natural disaster (Russoniello, Skalko, McGhee, Bingham-Alexander, & Beatley, 2002). Goenjian et al. (2008) found that even 6½ years after the earthquake in Armenia, adolescent children continued to experience depression. Among these adolescents, children who lost both parents were at a higher risk for depression. In a field study, Chemtob et al. (2002) explored the effects of living through a hurricane 1 year after the disaster. They found that children, including those who were previously treated, were still suffering from psychological problems, including generalized fear and problems associated with the death of a family member and physical injury (Chemtob et al., 2002).

Traumatized Children and Projective Techniques

Vizek-Vidovic et al. (2000) studied the effects of war trauma on children and argued that using children rather than adults, such as parents, as sources of information about the effects of trauma results in different findings. They suggest that parents tend to underestimate the effects of trauma on their children. Thus, it is important to focus on the reports of children when the effects of trauma in young children are of concern (Vizek-Vidovic et al., 2000). Yule (2001) and Falasca and Caulfield (1999) argued that traumatized children or children who have had various emotional problems have difficulty expressing their feelings and emotions. Woolgar (1999) stated that projective tests have been used reliably with children when the goal is to have children express their hidden feelings and emotions. When questions about an experienced trauma are asked explicitly, there is a possibility that children will not respond openly (Woolgar, 1999). Thus, when there is an absence of standardized tests and when it is emotionally difficult to handle being directly asked about the events experienced, controlled and consistent research can be planned by using projective techniques.

Some of the ways in which projective techniques are carried out in research is through the use of story completion, play, and children's drawings. Through the use of play and drawings, children can reflect their feelings of pain, fear, and helplessness (Gray Deering, 2000; Veltman & Browne, 2002). Not only do they express their feelings, they can also become active participants in the healing process (Falasca & Caulfield, 1999; Orr, 2007) Using projective techniques such as children's drawings has been reported to be safe and effective in helping children relieve pain (Malchiodi, 2001; Orr, 2007). Mercuri and Angelique (2004) noted that it is important to ask children about their postdisaster reactions and they need to be encouraged to express their feelings and thoughts verbally to ease their pain. This often helps children become more accepting of reality and facilitates a return to their normal lives (Shen & Sink, 2002). Previous research focusing on children's drawings after the Marmara disaster showed that children's drawings (with dark colors like black and brown) depicted disaster scenes including graves of parents or siblings (Celebi Oncu & Karaaslan, 2002). Another study carried out in the same disaster region with preschoolers' drawings showed that traumatized children tended to reflect their negative emotions about disastrous event in their drawings (Celebi Oncu, Akman, Guler, & Karaaslan, 2009).

Current Study

The goal of this exploratory study was to identify the consequences of the Kocaeli earthquake among children who were in kindergarten at the time the disaster struck. It was hypothesized that children who experienced the trauma of earthquake would still be feeling more negative thoughts 20 months after the disaster than children who did not experience trauma, when they are presented with a stressful situation. Because this study is one of the first of its kind using story completion as a projective technique to explore the inner workings of children experiencing disaster, the current study was designed as an exploratory study with a smaller sample size. The goal was both to understand the differences between the children's responses who experienced disaster and who did not and to explore whether a story completion as a projective technique could distinguish children's responses with exposure and no exposure to disaster.

To assess the types of negative and positive reactions young children would give to stressful situations, three different types of stories and three different types of questions were asked. In these stories, young children are presented with a scenario in which the main actor is facing some stressful event that shows similarities with the Kocaeli earthquake such as darkness, loud noise, shaking, trembling, and everything happening unexpectedly. The children were presented with incomplete stories and asked (a) how the story is going to end, (b) what the main character should do, and (c) how the child would end the stories. It was hypothesized that children who experienced trauma would give more negative responses to questions about how the story is going to end, and the children who did not experience trauma would give more positive responses and fight to change the situation. The second hypothesis was that the responses of the children who experienced trauma would report that the main character would be more likely to face trauma and injury, whereas children who did not experience trauma would be more likely to report survival of the main character and happiness. It was also hypothesized that if children are given a chance to end the stressful event themselves they would be less likely to end the stories negatively.

The specific predictions of the study were that the children who had experienced the earthquake disaster would complete the stories with negative answers more frequently than would children who had not experienced a disaster. Girls were expected to give more negative answers and complete the stories more negatively than boys as they were expected to be affected more by the disaster.

Method

Participants

The data for the current study were collected in May 2001. Two groups of children were included in this study. The first group of children (traumatized group) experienced the Kocaeli earthquake, while the second group (nontraumatized) did not. Because of the exploratory nature of the study a total of 103 children between the ages of 6.7 and 8.1 years (mean age = 7.4) at the time of the earthquake were selected to participate in this study. Participants in the traumatized group were selected from two elementary schools in the city of Golcuk, which is near the epicenter of the earthquake. The schools were selected because they were in the city center and most of the children in the schools were affected by the earthquake to some extent. Participants for the study group needed to meet two of three selection criteria. In addition to being physically present in the city of Golcuk when the earthquake hit, these criteria were to either lose a family member, to be physically injured themselves, or to experience destruction or serious damage to their homes. Out of these children, 84% of the children's houses were destroyed or seriously damaged, 23% had lost a family member, and 30% had survived the disaster with some physical injuries. The information about the types of trauma experienced by children was obtained from the families. At the time of data collection, the age of children in the traumatized group ranged from 8.4 to 9.9 years, with a mean of 9.1, and included 26 females and 27 males.

Children who were not victims of the earthquake were selected from the city of Kazan in Ankara Province. Kazan, which was 450 km away from the city of Golcuk, was selected, because the citizens living in this city did not experience the earthquake, and the two cities show some similarities in demographics. Even though Kazan, the city where the control group was selected, has a smaller population than the city of Golcuk, both cities have military bases; they both have industrial estates and are comparable in terms of their level of industrialization. The schools that were selected for the study are located in the areas where people come from middle socioeconomic status (Kazan and Golcuk municipalities). The elementary school in the city of Kazan was also located in the city center and there were a total of 450 primary school students enrolled in the school. A total of 50 children were selected to be in the control group. None of these children had experienced a life-threatening trauma by the time the data were collected. There were 25 females and 25 males in this group with ages ranging from 9.7 to 10.4 years, with a mean age of 9.8 years.

Materials

Three short and incomplete stories, which included words and descriptions used to remind children the earthquake, were prepared for this study (see Appendix A). The descriptions that were used to remind children of the earthquake were selected based on the general characteristics of the earthquakes, some of which are common for other natural disasters, and the specific features of Kocaeli earthquake. For example, the terms that were used in these stories to describe the event happening were "swinging and rocking back and forth, shaking, loud noises, things happening unexpectedly." In addition, because Kocaeli earthquake happened at 3:02 a.m., the stories included depictions of darkness. Even though stories used in the study included animals, plants, and inanimate objects, these aforementioned characteristics of an earthquake were used to describe the events which happened to the main characters in these stories. There were three short stories used in the study, one with a cat, the one with an ant, and a third with a tree as a main character. Each story was written in language appropriate for 9-year-old children. The teachers of children used in the study were given the stories first to determine whether the children could read and comprehend the stories without any help from their teachers. The children were read these stories and the questions associated with each story in their classrooms by one of the researchers (See Appendix B). These questions asked what happened to the main character, how the story ended and what the main character could do while the event was happening.

Procedure

The study was carried out in the children's elementary schools 20 months after the disaster. Data from the traumatized group were collected in April in two primary schools. Basic demographic information about the children was obtained from the children's parents. Although there were initially 30 boys and 30 girls in the study, 3 of the children refused to participate in the study and 4 did not meet the selection criteria. Thus, the responses of 53 children remained for analysis. The nontraumatized group was chosen as a comparison group from a primary school from a district of Ankara. The study was carried out in April with the traumatized group and in May with the nontraumatized group.

The children were assembled into groups of 10 to hear the stories. They were taken to a room where each child was seated separately, and each child was given a pencil and a sheet of paper. One of the authors remained with the children during the procedure. The researcher told the children:

> Now I'm going to read you some incomplete stories one at a time. Please listen carefully and when I finish each of these stories, I am going to ask you some questions about them. Please write your answers on the paper that is in front of you. You can take as long as you want. When you finish the first story, I am going to read the next story and we will repeat the same thing and answer the questions about that story.

Data Coding and Interrater Reliability

The authors, one of whom was completely blind to the children's situations including age, gender, and traumatic experience, coded the children's answers using the following procedure. First, both coders individually read children's answers and identified coding categories separately. Next, the coders met and shared the coding categories that they created based on the answers of the children. Similar codes were combined, and the codes that were different were examined and recreated by both coders. In the end, a total of seven coding schemas remained and the coders coded children's answers based on these coding schemas individually. After the first round of coding was completed, the agreement between the coders was established to be 88%, indicating that out of possible 824 answers, 97 of them did not match. Once the coders reviewed their answers and created one more coding category, the final category of codes reached to a total of eight. Once again the coders coded children's answers individually and in the end, when the answers of the coders were compared, it was found that the agreement between the coders reached to 96%, indicating a very good interrater reliability. To deal with the remaining 4% disagreement between the coders, those 34 responses of were examined by both coders cooperatively and an agreement was reached for 10 more items; the remaining 24 answers of the children that were either not clear, did not fit into any of the categories because of its content, or how it was written were labeled as missing. The coding schemas and their descriptions can be found in Table 1.

Statistical Analyses

For the statistical analysis, first the percentages of children whose answers fell for different categories were calculated for both traumatized and nontraumatized children and boys and girls for each of the three stories. Chi-square statistics

Table 1
Coding Schema and Children's Responses

Coding schema	General themes	Children's answers
Very negative	Death, destruction, serious injury, extreme distress	Killed; home was destroyed; train ran over the kitty; the roots of the tree came off and died; machine destroyed their home/neighborhoods; killed them . . .
Negative reactions	Distressed, scared, shaken, uncoordinated, upset, angry	Kitty got really scared; ant was afraid of the loud machine; kitty could not read his or her book; everything got dark; the leaves of the tree fell off; the ant was hungry . . .
Unsure	Not sure, trying to figure out what is going on, unaware	Kitty did not understand what was going on; looked outside to see what was going on; asked people to see what the noise was . . .
Sameness	Life goes on as it was before, unaffected, no traumatic consequence	Kitty went back to reading his or her book, nothing happened to the tree, did not fall, the machine just went away . . .
Good boy, good girl	Being calm, quiet, listening to what is said, following orders, being a good boy and a girl	Quietly waited for the noise/train/the machine to go away, wind to stop; listened to what is being said and obeyed; was a good kitty, did everything he/she was supposed to
Happiness	Happy ending, escaping from harm and danger, rescue, being safe	Kitty escaped, the tree/kitty/ant lived happily/very happily; ran away from danger for rescue . . .
Strength	Fighting against the destroyer, being strong, victory, building a new home	Stopped the train so that it would not destroy home/would not kill; stop the machine and kick it out of the forest; so strong stopping the wind . . .
Helping others	Caring for the others around, helping them, getting help/food for them	Went to look for siblings; rescued siblings and friends, brought food for others . . .

were reported to examine whether the numbers of children whose answers fell within different categories were statistically significant.

The next step in the analysis was to examine the differences between traumatized and nontraumatized children in terms of their negativity and positivity. To further the analyses, the answers of the children were recoded into a 4-point Likert scale for lower numbers to reflect high levels of negativity and high numbers reflect high levels of positivity. Even though questions asked for the stories were similar, because the characters and the events in the stories were different, the examination of the children for each of the story was carried out separately to investigate how each story made an effect on children's answers. To test this, three sets of multivariate analyses of variance (MANOVAs) were conducted.

Results

The first step in the analysis was to compare the number of children whose answers fell in different coding schemas based on child trauma status and gender. To examine the responses of children when they are presented with an incomplete story of a tree who is being shaken and tossed from side to side by a strong wind, cross-tabulations were computed, and the differences among children's responses were examined for statistical significance using chi-square analysis. When the children were asked about what happened to the tree in the story, it was found that traumatized children differed in their responses from children who were not traumatized, $\chi^2(3) = 8.72$, $p < .05$. It was observed that traumatized children were more likely to give either very negative responses (60%) such as the tree collapsing and its roots coming off or the tree dying, or negative responses (25%) such as the leaves falling, the three shaking form side to side, and feeling almost like it is going to come off from the ground. Even though the nontraumatized group was also likely to negative responses, fewer nontraumatized children gave very negative responses (38%) and more gave moderately negative responses (50%). Refer to Table 2 for a distribution of children's responses. The next common response for both the traumatized (15%) and nontraumatized (10%) children was that everything would stay the same, nothing would change, "the wind would probably shake the tree some, but, nothing would happen."

When children were asked about how they would end the story of the tree (see Table 3), differences between traumatized and nontraumatized

children were not observed, $\chi^2(5) = 2.43$, $p > .05$, indicating that there were no differences between traumatized and nontraumatized children in terms of how positively or negatively they would end the story of the tree. Results suggested that numbers of children who would have negative or severely negative endings for the story of the tree were similar among traumatized (30%) and nontraumatized (38%) children. Moreover, among traumatized children 28% reported that they would have happy endings for the story, while among nontraumatized children it was 30% of the children. Again, children ending the story by indicating that everything would stay the same and nothing would change if they were given a chance to finish the story was again similar for traumatized (34%) and nontraumatized (28%) children. There was no difference between boys and girls, $\chi^2(5) = 7.10$, $p > .05$.

Next, children's responses to an incomplete story about a kitten who is threatened by a loud train coming closer was examined. In the first question, children were asked about what happens after the kitten looks from the window and sees the train and the electricity in the whole city is cut. Results revealed that children from traumatized group differed in their responses from the nontraumatized group, $\chi^2(6) = 15.46$, $p < .05$. It was found that more children in the traumatized group (86%) gave responses that were very negative than the no-trauma group (14%). When children's responses within trauma and no-trauma groups were examined separately, it was found that the majority of the traumatized children gave either negative (45%), or very negative responses (23%), whereas the majority of the nontraumatized children gave responses that were either moderately negative (39%) or positive (38%) with reports of strength, escape, and happiness. Very negative responses of the children included "the kitten would be hit by the train and die" and "the train would run over the kitten," while the negative responses included statements such as "the kitten would be scared from the loud noise, could not read his or her book, the electricity would stay cut." A number of nontraumatized children reported that everything would be the same (14%), "the kitten would continue reading, would look from the window and go back to what he or she was doing" (see Table 4).

No gender effects were observed, $\chi^2(6) = 10.43$, $p > .05$.

Interestingly, however, when the children were asked about how the kitten story should end, no statistically significant differences between children from trauma and no-trauma groups were observed, $\chi^2(6) = 6.82$, $p > .05$ (see Table 5). The children who report a happy or positive ending for the story seemed to be similar, with 78% the nontraumatized children and 67% of the traumatized children (see Table 3). The happy ending responses included, "I would want the kitten to be happy, go back happily and read his or her favorite book, the kitten would be very happy to see the train." The responses that had strength and courage included "the kitten would stop the train so that the train would not hurt anybody." No sex differences were observed, $\chi^2(6) = 5.78$, $p > .05$. Refer to Table 2 for a distribution of children's responses.

The last question about the kitten asked children how they think the kitten should behave or respond. Even though there were some differences observed, they did not reach the levels of statistical significance set for the present study, $\chi^2(7) = 13.18$, $p = .07$. It is worth noting that only one traumatized child and no nontraumatized child gave a very negative response to this question, and only 2 traumatized children and 6 nontraumatized children gave somewhat negative responses. The majority of the children reported that the kitten should behave well (good boy/good girl) with 54% of the nontraumatized, and 43% of the traumatized children giving such responses (see Table 6).

The final story presented to the children in the study was about a hard-working ant who, while

resting at home in the forest, hears a loud machine going through the forest and knocking down the trees. The first question asks children about what happens next. It was found that even though children reported various responses the difference between the responses of children from trauma and no-trauma groups was not at the levels of conventional statistical significance, $\chi^2(7) = 13.25$, $p = .07$. Of the traumatized children, 34% reported that something very negative would happen. These responses included the "ant dying, everything being torn down and nothing surviving and other people dying." Nearly 23% of them reported that something moderately negative would happen such as the ant would be scared, they could not find food, they would be upset, ant could not find his or her siblings. Nearly, 20% of the nontraumatized children reported helping others in need while only 11% of the traumatized children reported such behaviors. Over 18% of the nontraumatized children reported strength and courage, and over 11% of the traumatized children gave similar responses. These strength responses included "fighting against the machine," challenging it by yelling at it "to stop hurting the forest and the animals," "stopping it, kicking it out of the forest, building their homes and/or the forest back finding a lot of food to eat" (see Table 7). No gender differences were observed

in children's responses, $\chi^2(7) = 8.72$, $p > .05$. Refer to Table 7 for a distribution of children's responses.

The next question asked children how they would end the ant story. No differences between the trauma and the no-trauma children were observed, $\chi^2(7) = 5.59$, $p > .05$. Similar to the story about the kitten, when children were asked how they would end the story, the negative responses were fewer than the positive responses (see Table 8). It was found that over 76% of the traumatized children reported that if it were them they would have a positive ending for the ant story, with nearly 10% reporting that everything would stay the same and life would go on as usual, over 34% reporting happy ending, nearly 26% reporting strength and courage to fight back, and nearly 8% reporting helping others. Interestingly, reports of positive endings for the story was also 74%, with 2% reporting that everything would stay the same, 34% reporting a happy ending, 24% reporting courage and strength, and 14% helping others. No significant gender differences were observed, $\chi^2(7) = 10.63$, $p > .05$.

When the children's responses to the final question about what the ant should do while the events were happening were examined, it was found that again, there were no significant differences between the trauma and the no-trauma groups, $\chi^2(6) = 9.62$, $p > .05$. Similar to the question about how they would end the story, the responses of children from both groups were positive. Of the traumatized children, 94% gave positive responses, with 26% happiness, 28% strength, 30% helping others, and

10% being a good boy or a girl. Almost all, over 98%, of the nontraumatized children gave positive responses, with over 8% reported doing the usual things, over 18% reporting happiness, nearly 43% reporting strength and courage, over 18% helping others, and over 10% reporting being a good girl and a boy. Refer to Table 9 for a distribution of children's responses.

The next step in the analysis included comparing traumatized and nontraumatized children in terms of their negativity and examining the interaction effects of trauma and gender. Three sets of MANOVAs were conducted to test the difference between children for each of the three stories. When children's negativity was examined for the story about a tree, multivariate analysis did not reveal a significant interaction effect, $F(2, 98) = 0.19$, $p > .05$; or main effects of gender, $F(2, 98) = 2.06$, $p > .05$; or trauma, $F(2, 98) = 1.06$, $p > .05$; nor were there any significant univariate effects of gender or trauma.

The next step in the analysis included assessing how negative or positive the children's responses were in response to the story about the kitty. Examination of the multivariate analysis did not reveal a significant interaction effect of gender and trauma, $F(3, 91) = 1.3$, $p > .05$. Multivariate analysis did, however, reveal a significant main effect of trauma, $F(3, 91) = 6.94$, $p < .05$, $\eta_p^2 = .19$, but no significant effects of gender, $F(3, 91) = 2.47$, $p > .05$, were found. Examination of the results of the univariate analyses did not reveal a significant interaction effects of gender and trauma for how the story ends, $F(1, 96) = 1.95$, $p > .05$; how the story should end, $F(1, 96) = 1.21$, $p > .05$; and how the kitty should behave, $F(1, 96) = 0.45$, $p > .05$. There was however, a main effect of trauma on children's responses about how the story ends, $F(1, 96) = 12.8$, $p < .05$, $\eta_p^2 = .12$, indicating that traumatized children ($M = 2.12$, $SE = 0.12$) ended the stories less positively than children who were not traumatized ($M = 2.73$, $SE = 0.12$). There was also a main univariate effect of trauma on children's responses about how the kitty should behave, $F(1, 96) = 6.71$, $p < .05$, $\eta_p^2 = .07$, indicating that traumatized children ($M = 3.36$, $SE = 0.09$) reported more positive responses than the nontraumatized children ($M = 3.04$, $SE = 0.9$). Another significant univariate finding was the significant main effect of child sex on how the kitty should behave, $F(1, 96) = 4.15$, $p < .05$, $\eta_p^2 = .04$, indicating that girls ($M = 3.08$, $SE = 0.9$) were less positive than boys ($M = 3.32$, $SE = 0.9$).

The final step in the analysis was to assess the negativity of children's responses when they were presented with the story of an ant with a loud machine in the forest based on their sex and whether they were traumatized. Multivariate analyses did not reveal an interaction effect of gender and trauma, $F(3, 91) = 1.39$, $p > .05$, or a main effect of gender, $F(3, 91) = 1.53$, $p > .05$. Multivariate analyses however, revealed a significant main effect of trauma, $F(3, 91) = 3.12$, $p < .05$, $\eta_p^2 = .09$. Examination of the results of univariate analyses indicated that child sex and trauma did not have significant interaction effects on for how the story ends, $F(1, 93) = 2.04$, $p > .05$; how the story should end, $F(1, 93) = 0.21$, $p > .05$, and what the ant should do, $F(1, 96) = 1.79$, $p > .05$. Further examination of the univariate analysis indicated that child trauma had a main effect on children's responses to how the story ends, $F(3, 91) = 12.91$, $p < .05$, $\eta_p^2 = .09$. Expectedly, traumatized children ($M = 2.53$, $SE = 0.17$) were more negative (less positive) than children who did not experience trauma ($M = 3.26$, $SE = 0.17$). Trauma, however did not have any univariate effects on how the story should end, $F(1, 93) = 0.19$, $p > .05$, and what the ant should do, $F(1, 93) = 0.02$, $p > .05$. The univariate effects of child sex was examined and no statistically significant effects were found for how the story ends, $F(1, 93) = 0.38$, $p > .05$, and how the story should end, $F(1, 93) = 1.21$, $p > .05$. Even though not significant at the levels of conventional significance, a trend toward statistical significance was observed for univariate gender effects on what the ant should do, $F(1, 93) = 3.78$, $p = .06$, $\eta_p^2 = .04$, indicating that girls ($M = 3.63$, $SE = 0.08$) demonstrated less positivity than boys ($M = 3.89$, $SE = 0.08$).

Discussion

This study examined the long-term consequence of experiencing a natural disaster. Traumatized children's and nontraumatized children's views about disastrous events appeared significantly different. Traumatized school-age children who witnessed or experienced destruction, grief, pain, and life threat, almost 2 years prior to the research, reported more negative thoughts about events that have themes similar to the trauma they experienced. This may be the consequence of the trauma, as the children could still be suffering postdisaster reactions. In a study carried on the same disaster region with preschoolers, when children were requested to tell stories about some emotional drawings, it was found that children's stories were mainly and significantly related to the disaster (Celebi Oncu et al., 2009).

In the present study, it was found that children who were directly affected by the earthquake could still be suffering significant traumatic effects 20 months after the event as they were more likely to have negative thoughts and end stories more negatively. This finding is similar with other studies of traumatic events (Chemtob et al., 2002; Najarian et al., 1996; Shaw et al., 1996; Shen & Sink, 2002; Winje & Ulvik, 1998; Wolmer et al., 2005). These studies showed that 1 or 2 years after disasters, children were still suffering trauma symptoms and they noted that children reported a fear of death or being physically hurt after disasters.

An important finding in this study is that in order to interpret the responses of children to trauma, it is necessary to distinguish between the children's anticipations about how the events will end and how children would like the event to end. Traumatized children demonstrated more negativity about the consequences of events when they felt they could not change the course of events. It appears that when they are given a chance to end the story themselves, "how would you end the story," they are more likely to have less negativity and more positive descriptions. Interestingly, for example, in the story of the tree, both traumatized and nontraumatized children were thinking that the end of the story, when it is outside of their control, would be negative. However, traumatized children were more likely to give severely negative responses than nontraumatized children. When the children were asked how they would end the story, an opportunity to change the course of events, no significant differences appeared to emerge between the trauma and no-trauma groups. In fact, the number of children giving a happier ending to the story increased in both groups. Similarly, in the story of the kitten, the majority of the traumatized children reported either negative or very negative responses while the nontraumatized children completed the stories either with positive or less negative responses. Again, when the children were asked about how they would end the story, the differences between the trauma and no-trauma groups disappeared. Even though there were slightly more positive responses among the no-trauma group, children from both groups were much more positive in their responses. Similarly, in the story of an ant, when children were asked how they would end the story, the responses were more positive overall and no differences emerged between the groups.

Another interesting finding that emerges from this study is that both groups of children were more negative when they were asked about a tree. This was clear both when they were asked to anticipate an ending for the story and determine an ending for the story as well as when their responses were analyzed independent of the type of the question that is asked to have children come up with an ending. Children's responses were less negative and more positive when the question was asked about the kitten and the ant. It is possible to speculate that children see trees differently from animals. Future studies should explore whether these findings about children's different responses to expected and desired endings are reflective of more general differences in life outlook between the traumatized and nontraumatized children.

In the present study, male and female children were expected to complete the stories differently. We had hypothesized that girls would show more negative effects from the disaster and that they would complete the stories with more negative and emotional explanations, and boys were expected to complete with more aggressive explanations. The results indicated that when children were asked about how the kitty should behave, the girls were more negative than the boys and they also reported more negativity when they were asked about how the ant should behave. Results of the present study did not show substantial gender effects to draw any conclusions. However, even though the differences were very small, nontraumatized boys were more negative than the nontraumatized girls. Attachment research has shown that young boys show more negative behaviors because they are more vulnerable than females to deprivation of warm affectionate maternal supportiveness (Honig, 2002). The present study did not assess the effects of the types of trauma children experienced. We do not know anything about these children's conditions at home to make and substantial conclusions about the gender effect. It may be one reason for why the findings were not consistent with the literature. Dewaraza, Sato, and Ogawa (2006) reported that tsunami-affected boys were more anxious and had more negative psychological reaction compared to girls. However, many previous studies have shown that traumatized girls demonstrated a significant increase in the levels of anxiety, stress, or depression in comparison with male children (Giannopoulou et al., 2006; Goenjian et al., 1995; Shaw et al., 1996; Vizek-Vidovic et al., 2000; Yule, 2001). More research on gender differences in response to traumatic experiences needs to be done to clarify the variables that may result in conflicting findings.

Implications and Future Directions

Traumatizing events are difficult for most children. The findings of this research indicated that traumatized children were still suffering from the earthquake disaster nearly 2 years later. They expressed more negative thoughts about disaster events in response to the story stems they heard. Although the study design was simple and was not confirmed by additional instruments, the uncompleted stories seemed to be an effective tool to expose the traumatized children's feelings about traumatic events. This was especially evident in considering the answers given by the contrast group compared with the traumatized group. While the children in the contrast group gave more positive answers, the traumatized children's answers tended to be more negative. These differences provide evidence for possible long-term effects of catastrophic disaster on children's thoughts and feelings.

Findings also showed that traumatized children preferred to complete the stories with happy endings if they felt that they are in charge. It could be hypothesized that traumatized children want to get rid of their stressful inner feelings and want happiness in their life again. They have positive desires, yet when they are asked about how things will be around them, they still feel that things will be negative. Thus, it is very important to support these children's feelings that they are in charge. These are hopeful findings for future resiliency and healing from trauma in children's lives. Disaster experiences may linger in the thoughts and ideas of traumatized children. Their positive responses, however, should give hopeful determination to counselors and therapists working in schools and with families that children have possibilities for resiliency and recovery that may be much more difficult for adults to achieve. Moreover, future research on sufferers of trauma, particularly natural disasters, should investigate the dynamics of learned helplessness among children.

Future research needs to include other projective techniques or more variations on incomplete stories that probe for children's responses to disasters. Therapists reading some children's very negative story endings will want to focus their efforts on easing children's traumatic symptoms such as PTSD, grief, anxiety, or depression and provide more reassurances and supports for healing.

Stories or children's literature can also be effective tools for children to recover. Children should be given chance to open their minds, to tell their stories, and to talk about their feelings, thoughts, and concerns about their trauma experience. Bibliotherapeutic books or stories could be used for children to recover and express themselves. Traumatizing events such as disasters are unexpected events. Prevention programs might focus on building up techniques of positive coping skills for children and families and increasing the levels of self esteem and decreasing the levels of learned helplessness.

This study showed that simply asking the question differently revealed such striking differences in children's responses. It is therefore important that future research designs allow for children to give their answers under different conditions in which we can really understand what they want, what they think will happen, what they would desire to happen, and what they think others expect to happen.

Study Limitations

Although the findings of this exploratory study are important for many reasons, there are still significant limitations of the study requiring future research. In fact, this is only amplified because of some of the interesting finding the study revealed. The narrative stories used for the study and the coding categories established were developed for the first time for the current exploratory study. Thus, there was no established validity for the stories or for the codes. Future research is needed to be conducted with Turkish children for cultural validity and with children from different cultures for construct validity. Another important limitation of the study is that we did not control for the types of trauma children experienced and how these experiences affected the responses children provided. We also do not know anything about the recovery and the healing process of the children and their families. Experiences of these children after the earthquake would influence them to have more positive or negative views about life. Another limitation of the study is not including the overall quality of the home environment in the study. Next, because of the exploratory nature of the study, the sample size was fairly small, thus preventing us from any generalizations and conclusions. On the other hand, it provides some interesting findings and directions for future research. Consequently, it is essential that future research be conducted with more children and children from different socioeconomic backgrounds and varying proximity to the earthquake and varying degrees and types of trauma experienced at the time of the earthquake would allow for obtaining more insightful information. Moreover, it is also important to use similar projective techniques for children with different types of trauma to understand the inner workings of young children who face disaster and trauma. Longitudinal studies need to be carefully designed to track down how children deal with trauma and under what conditions healing occurs.

Appendix A

Story 1: A Story About a Tree

There was once a tree living happily on a hill with its roots reaching deep in the ground. It lived many days and nights, and had many beautiful days. One day on the top of the hill where the tree lived a strong wind began blowing. The branches of the tree were moving from side to side. The wind was so strong it felt like the roots of the tree were going to come off.

Story 2: Kitty in the Darkness

A little kitty was sitting happily in its cozy home looking at the pictures of its favorite book. All of a sudden she started hearing the noise of a train coming closer and the sound of the train was getting louder and louder. The kitty left her book and went to the window to look outside. Right at that moment, the power of the whole city was cut.

Story 3: The Ant and the Buldozer

There was once a hard working ant who lived in a forest. This ant was always carrying food home and preparing for the winter. Finally the winter came and the ant went to its home underground. One day a bulldozer came making loud noises, bothering the animals and knocking down the trees on its way to dig a big hole in the ground. The ant hears the noise and goes outside to its siblings to see what is going on.

This study examines the impact of children's exposure to natural disaster against the backdrop of exposure to other traumatic events and psychosocial risks. One thousand three hundred ninety-eight Sri Lankan children aged 9–15 years were interviewed in 4 cross-sectional studies about exposure to traumatic life events related to the war, the tsunami experience, and family violence. Symptoms of posttraumatic stress disorder, somatic complaints, psychosocial functioning, and teacher reports of school grades served as outcome measures. A global outcome variable of "positive adaptation" was created from a combination of these measures. Data showed extensive exposure to adversity and traumatic events among children in Sri Lanka. Findings of regression analyses indicated that all 3 event types—tsunami and disaster, war, and family violence—significantly contributed to poorer child adaptation.

The vast majority of data on the psychological impact of children's exposure to disasters come from developed countries (Norris et al., 2002). Nonetheless, the enormity of the power of disasters on life in the developing world requires a consideration of their impact on children's development and adjustment: Deaths from natural disasters in the developing world account for 95% of deaths from disasters worldwide (World Bank, 2006). Moreover, particularly in politically unstable regions, exposure to disaster often co-occurs with exposure to other traumatic events, such as armed conflict and family violence (e.g., Catani, Jacob, Schauer, Mahendran, & Neuner, 2008), and other psychosocial risks, including extreme poverty. Although difficult to accomplish, studying children in such contexts offers a special opportunity to understand the contribution of exposure to single-disaster incidents compared with other traumatic stressors and cumulative risk on children's functioning and development.

Data from four cross-sectional studies examining the functioning of Sri Lankan (primarily Tamil) schoolchildren over the period 2002–2006 are reported in this study. The time periods of these studies (i.e., prior to and following the tsunami of 2004) provide for snapshots of traumatic risk and functioning among a child population exposed to a

---

The data of this study were collected in the context of a cooperative humanitarian project of the Zonal Department of Education Vallikamam, the Shantiham counseling center, the German Technical Cooperation (GTZ), and the nongovernmental organization vivo. We are grateful to all children, teachers, counselors, and staff members in Sri Lanka who took part in the studies. The research conducted in these studies was supported by the DFG (Deutsche Forschungsgemeinschaft), "Ein Herz für Kinder" foundation, and vivo. The authors would like to thank Mahendran Kohila and Nadja Jacob for their special contribution to training of local counselors and supervision of data collection. In addition, we would like to thank Daya Somasundaram and Sundaram Divakalala from GTZ for supporting the research in Sri Lanka with their continuous professional and logistical input. Authors declare they have no conflict of interest. The corresponding author had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

variety of highly stressful events, including war, natural disaster, and family violence. Next, we provide a conceptual developmental framework and rationale for the current research, as well as an overview of the context of war and natural disaster in Sri Lanka.

A Risk and Protection Framework for Children's Functioning

Studies, primarily undertaken in the developed world, have revealed the importance of understanding children's functioning in the contexts of environmental risks, vulnerabilities, assets, and protective factors or processes (e.g., Garmezy, 1993; Masten, 2001; Rutter, 1987; see Masten & Gewirtz, 2006, for a definition of terms). Of particular relevance is the observation that among children living in "high-risk" situations—that is, exposed to events that may potentially impair their health or development—risk factors tend to co-occur and to "pile up" (Sameroff, Seifer, Zax, & Barocas, 1987). For example, children who witness interparental violence are at significant risk for maltreatment (Edleson, 1999); children exposed to war or natural disasters are particularly vulnerable to "secondary adversities" such as homelessness, parental loss, and community violence (Pynoos, Steinberg, & Piacentini, 1999).

Given these observations, there has been an increased focus in the child development field on examining the effects of *multiple* risks rather than the nature or power of specific individual risks in the context of children's adjustment (e.g., Kraemer et al., 1997). Risk factors are considered to act cumulatively in the sense that the presence of more risk factors in a child's life is related to an increased likelihood of negative adaptation. Thus, studies of risk incorporate several possible different types of risk factors as predictor variables that are hypothesized to elevate the likelihood of undesirable outcomes in children's adjustment. Rutter (1979) found that the number of risk factors, more than any specific risk factor, accounted for increased risk of psychopathology in children. Subsequently, studies have shown consistent relations between risk and functioning, with increased risk associated with poorer functioning in developmental domains (e.g., Gutman, Sameroff, & Eccles, 2002).

This literature provides a valuable, broad "brush stroke" in demonstrating the influence of the quantity of risk factors to which a child is exposed, regardless of the type of risks. Also consistent with a risk and protection framework in children's development is the examination of outcomes that cut across developmental domains rather than being limited to a single domain (e.g., psychopathology). Thus, consistent with the literature indicating correlates of healthy development at different developmental stages, studies of risk and resilience have incorporated outcome measures that include social, academic, and psychopathology indicators (Masten & Coatsworth, 1998; Werner & Smith, 2001).

In contrast to a broader risk framework, studies specifically focusing on trauma more typically have investigated the impact of exposure to a single traumatic stressor or particular class of stressors (e.g., maltreatment, war, etc.) on individual child outcomes (e.g., the presence or absence of psychopathology; La Greca, Silverman, Vernberg, & Prinstein, 1996). As a result, this literature has seen relatively less focus on the broader context of children's development (e.g., Pynoos et al., 1999). However, somewhat in parallel to the broader risk literature described before, studies consistently have documented a dose–response effect with regard to the number, types, and severity of trauma events experienced by children. That is, the closer a child's proximity to a traumatic event, or the more events experienced, the more likely a child is to experience posttraumatic stress disorder (PTSD; e.g., Hubbard, Realmuto, Northwood, & Masten, 1995; Neuner, Schauer, Catani, Ruf, & Elbert, 2006). We could find no studies of trauma, however, whose outcome variable was children's overall adjustment rather than specific psychopathology. We could also find no studies examining the effects of exposure to multiple different traumatic events (i.e., events of a different trauma class) compared to exposure to a single event type (e.g., war or domestic violence alone).

Investigating the risk context is consistent with efforts to incorporate the broader environment (i.e., family, community, and society) in understanding influences on children's development (e.g., Bronfenbrenner, 1979). This risk and resilience and positive adaptation perspective may be especially important for studies in the developing world, where children's lives are so frequently marked by traumatic events and severe adversity, and where little data have been collected to describe children's adaptation in these contexts. Bronfenbrenner's (1979) bioecological systems theory adds to this developmental and contextual perspective by framing risk and resilience within multiple and interlocking systems operating in a child's life. The bioecological approach emphasizes that a child's own biology is a primary environment fueling his or her development. The interaction between factors in the child's developing biosystem, his or her immediate family and community environment, and the societal context both fuels and guides children's developmental pathways. Changes or conflict in any one layer will have ripple effects throughout other layers (Berk, 2000). To study a child's development, then, we must look not only at the child and her immediate environment but also at the interaction of the larger co-occurring environments across micro-, meso-, exo-, and macro-level systems (Berk, 2000). Below, we describe the context of this study, and outline a rationale for gathering basic information about both traumatic stressors and children's adaptation in a developing world context.

The Context of Risk in the Developing World: War and Natural Disaster in Sri Lanka

When studying risk and resilience in children affected by trauma, insights from developing world countries where children are often affected by a variety of profound risks to life, health, and development are of high importance. In particular, descriptive data are needed that not only describe the contribution of traumatic risks to adjustment but also allow for conclusions about the relation between the amount of various types of trauma exposure and adaptation in children. In this regard, Sri Lanka, where a major natural disaster was preceded by a long-lasting civil war, offers an unfortunately valuable opportunity to assess the larger context of risk in childhood. Specifically, this context enables us to investigate the influence of exposure to different types of traumatic stressors (i.e., multiple risks), as well as the relation between the extent of exposure to each stressor type and adaptation.

In Sri Lanka's North-Eastern provinces, in particular, traumatic experiences were already common prior to the tsunami in December 2004. For two decades, thousands of people had been killed and many more were displaced as a result of conflict and violence in the country. The Liberation Tigers of Tamil Elam (LTTE) have been fighting for political autonomy resulting in ongoing conflict in the northern and eastern areas of the country. Civilians have become casualties of war, landmines and unexploded ordnance pose a constant threat, hospitals and schools have been destroyed, and the economy has been shattered. In spite of a cease-fire that was called in December 2001, violent incidents between the LTTE and the government have recently dramatically intensified, costing the lives of several thousand people over the last 2 years.

Since early 2002, our workgroup had been partnering with the German Technical Association, the Ministry of Education, the Education Council North-East, and the Shantiham Association for Health and Counseling to build up a cascade-model of psychosocial care for affected children in the North-Eastern provinces of Sri Lanka. The framework of this model consisted of over 1,000 teachers being trained to identify children with psychological impairments in schools. A selection of 150 of the most qualified teachers were trained as counselors to provide services to children in need. Over this period of time, four epidemiological surveys were carried out with Tamil school children, two studies prior to and two subsequent to the tsunami. The overall aim of these studies was to establish the severity of war-related (and later also tsunami-related) exposure to trauma in Tamil children and its impact on their mental health.

The first study was conducted in the Vanni area very shortly after the ceasefire agreement at the end of 2001 and showed that 92% of the children had experienced traumatizing war-related events and 25% of the sample met the criteria for a PTSD diagnosis (Elbert et al., 2008). These results were confirmed by a similar follow-up study in the Vallikamam and Jaffna educational zones 2 years later (Catani et al., 2005), where 80% of the interviewed school children had been traumatized by the war. The PTSD prevalence rate for children was 18% with the "traumatic load" (number of experienced event types) being significantly linked to the development of PTSD.

This finding led us to use the so-called dose–effect in further conceptualizing and understanding the impact of traumatic exposure on mental health (Neuner et al., 2004). This association was further established in the third epidemiological survey carried out 4 weeks after the tsunami hit Sri Lanka in December 2004. Results showed that the prevalence of PTSD in Sri Lankan children affected by both the civil war and a natural disaster was as high as 40% after the tsunami with PTSD rates being best explained by the severity of exposure to tsunami-related traumatic events and previous war experiences. To further extend the assumption of a dose–effect model to other types of stressors in the lives of children, in a subsequent study we included experiences of family violence as a potential risk factor for mental health impairments in Sri Lankan children (Catani, Jacob, et al., 2008). Apart from presenting a high prevalence of abusive experiences at home, results from this study showed that family violence, experienced or witnessed by children, ought to be taken into account when investigating the cumulative effects of various forms of stressful experiences on children's well-being.

The finding about the critical impact of family violence on children's mental health encouraged us to reanalyze all the data from the previous study and to take into consideration information about the experience of family violence, which had been assessed but was not included in previous data analysis. Furthermore, we wanted to not only focus on PTSD as the outcome measure but also to take into account the variety of outcome variables that had been assessed in the surveys (i.e., somatic complaints, school grades etc.) and combine them into an index for children's overall adjustment toward risk.

In summary, we broaden the investigation of the impact of traumatic events on children's functioning by applying a risk framework to the study of children's exposure to traumatic events in a highly stressful developing world arena. In this context, we were interested in (a) understanding the nature and influence of different types of traumatic stressors (risks) on children's functioning and (b) understanding children's positive adaptation in the broader developmental and environmental context (i.e., academic and social and health functioning, as well as absence of psychopathology).

Research questions related to the analysis of the four data sets were as follows:

1. How are different stressors associated with children's adaptation following exposure to war or tsunami?
2. Does assessment of a broader, more detailed range of risks/traumatic events result in more variance explained in children's adaptation?
3. Are both the multiplicity of risk (defined by the number of different risk categories a child is affected by) and trauma severity (defined by the number of single event type within a specific risk category) predictive of children's adaptation?

This last question, aimed at disentangling severity and the extent of different trauma types and multiplicity of risk, was based on DataSet 4 only, as this was the only study where continuous measures for risk and trauma severity were used.

Method

Samples and Procedures

Data presented here are taken from four independent epidemiological surveys that our workgroup conducted at different time points in different geographical areas of Sri Lanka. Details of the single surveys with respect to both methods (sampling strategy, data collection, instruments) and results have been published elsewhere (Catani, Jacob, et al., 2008; Catani et al., 2005; Elbert et al., 2008; Neuner et al., 2006), and will therefore not be addressed in full detail in the present study.

All studies were designed as surveys of school-attending children or—in the case of the Tamil children interviewed right after the tsunami—of school-aged children in a temporary shelter for internally displaced people. All participants were randomly selected from the respective populations. Within the schools included in Surveys 1, 2, and 4, participants were randomly selected on the basis of an index including classes with children of a certain age range. For every class, every other to every fifth child (depending on the size of the class) on an alphabetically ordered list was chosen and invited to participate in the survey. The study population in the immediate aftermath of the tsunami (Study 4) also included a sample of children recruited from a provisional refugee camp in Manadkaddu. All eligible children aged 8–14 who were present on the day of the interview were included in the survey. The four samples that were included in the present data analysis comprised a total of 1,398 children from different parts of Sri Lanka, mainly the Tamil North-Eastern region of the country.

Study 1 (Vanni). In Study 1 (Elbert et al., 2008), fifth-grade children from 15 different schools randomly chosen from all five administrative zones of the Vanni region of Sri Lanka participated in the survey. Vanni is a region under the control of the LTTE enclosed on the east and west by the sea and on the north and south by no-man zones at military lines that were established by the ceasefire agreement signed in 2002 between the government of Sri Lanka and the LTTE.

Sample 2 (Vallikamam). Study 2 (Catani et al., 2005) was conducted with children of six different schools of the Vallikamam and Jaffna educational zones in the north of Sri Lanka.

Sample 3 (Manadkaddu, Galle, and Kosgoda). Study 3 (Neuner et al., 2006) was carried out 1 month after the tsunami, in January 2005, in three severely affected communities of the country. The village Manadkadu in the Vadamarachi region in northern Sri Lanka was completely destroyed by the tsunami. Like many communities in the North-Eastern provinces, Manadkadu had been severely affected by the Sri Lankan civil war already, prior to the natural disaster. In contrast to the other surveys comprised in this study, Study 3 included not only children of the Tamil population of the North-East of Sri Lanka but also two locations in the Singhalese part of the country that had not been affected by the civil war. However, both regions—Kosgoda (western Sri Lanka) and Galle (southern Sri Lanka)—are coastal areas, and were both devastated by the tidal wave.

Sample 4 (Point Pedro). The most recent study (Catani, Jacob, et al., 2008) was conducted approximately 1 year after the tsunami in the Vadamarachi school district (Point Pedro area) at the northern tip of Sri Lanka. Being an important strategic point during wartime located right by the sea, Point Pedro had been severely exposed to two decades of civil war before it was hit by the natural disaster at the end of 2005. Table 1 provides an overview on location and time period of data collection in the four studies and on sociodemographic characteristics of the different child samples.

Procedures. In all surveys, informed consent was obtained from both the child and one of her caregivers or parents. Approval for implementation of the studies in Sri Lanka was obtained from the Ethical Review Board of the University of Konstanz, Germany. All surveys were carried out in cooperation with and approved by Sri Lanka's Ministry of Education. Interviews were conducted by former schoolteachers who had previously been trained as "master counselors" (Schauer et al., 2005) to assist traumatized children. Interviews conducted by local counselors were closely supervised by one or more clinical psychologists from our work group.

Measurement

Following the hypotheses derived from the theoretical background, we sought to measure a variety of risk factors including economic deprivation, loss of family members, family violence, violence associated with the war, traumatic events associated with the tsunami, and other traumatic experiences in each study. Psychosocial adaptation was the common outcome measure of the analyses. We created an adaptation index based on the following variables: somatic symptoms, PTSD symptoms, psychosocial functioning, and school performance. However, data presented here are a reanalysis of four independent studies where parts of the same and different instruments and outcome measures had been used. Table 2 provides an overview of independent variables and outcome measures for each survey to further clarify areas of methodological overlap versus differences between the studies.

Economic status. To reduce the amount of variables in the analyses, we constructed a single global measure of economic status from data related to economic factors in the surveys. The index of economic status was calculated as the mean of standardized (z-transformed) variables related to child possessions, family possessions (assessed using an asset checklist of typical items), and meals per week.

Family loss. In Studies 1, 3, and 4, the number of core family members who died was assessed by asking "How many of your family members, including your parents and siblings, have died so far?" In Study 2, only the loss of parents was assessed by a yes or no answer to the question "Did either your father or your mother die?"

War experiences. In Studies 1 and 4, war experiences were quantified using a war-related event checklist (Catani, Jacob, et al., 2008). In Studies 2 and 3, the event checklist of the University of California at Los Angeles (UCLA) PTSD Index (UPID) for children (Pynoos, Rodriguez, Steinberg, Stuber,

[a]Not assessed. [b]Not applicable.

& Frederick, 1998) was employed to assess exposure to the war. Previous exposure to the war was ascertained with a dichotomous measure to which children answered "yes" or "no" to the UPID event checklist item "being in a place where a war was going on around you" (Item E4).

Family violence. Based on the available data of each survey, in Studies 2 and 3, family violence was assessed by children's responses to the two UPID event checklist items referring to family violence: "being hit, punched, or kicked very hard at home" and "seeing a family member being hit, punched or kicked very hard at home" (Items E5 and E6). In the Point Pedro sample (Study 4), the amount of family violence was defined as the number of questions answered positively on the family violence event checklist. In the latter study, an additional 30-item questionnaire was utilized to assess the quantity of adverse childhood experiences at home (Catani, Jacob, et al., 2008). It is important to note that the checklist about family violence included a variety of experiences ranging from slightly aversive events occurring at home (e.g., being threatened verbally) to experiences that fall in the range of traumatic life events (e.g., having been threatened with a weapon).

Severity of exposure to the tsunami. To estimate the severity of tsunami exposure in the two post-tsunami samples, five questions related to the tsunami experience were added to the interviews (Catani, Jacob, et al., 2008; Neuner et al., 2006). For instance, children were asked "Did you see the big wave close by?" and "Were you caught by the wave?" The five questions were answered "yes" or "no." The score for objective Tsunami exposure was the number of "yes" answers.

Exposure to other traumatic experiences. To obtain a more complete representation of traumatic events as potential risk factors in the lives of Sri Lankan children in the analyses, we included additional items of the UPID event checklist where available. These items could not unambiguously be assigned to the context of war, family, or disaster, and could also be related to community violence. The items related to physical attack ("being beaten up, shot at or threatened to be hurt badly in your town"), witnessing physical attack ("seeing someone in your town being beaten up, shot at or killed"), having seen a dead body ("seeing a dead body in your town"), or experiencing sexual violence ("Having an adult or someone much older than you touch your private sexual body parts when you did not want them to").

Multiplicity of risks. In Study 4, in addition to the continuous measures of severity of a specific risk or trauma type, we created an index of multiplicity of risk defined by the number of different risk categories a child had been or was currently exposed to. Risk categories that could be determined were the experience of war, the experience of family violence, the experience of the tsunami, and the loss of a parent. On the basis of children's answers to the UPID event questions for war and for family violence, children were classified as either being affected by the specific risk category or not. With respect to the tsunami, children were classified as "having been exposed to the tsunami" if their tsunami severity score was > 0.

Adaptation score. A global adaptation score was calculated as the mean of z-transformed values of the following outcome measures that had been included in the four surveys (descriptive statistics with respect to the single outcomes, such as PTSD symptom score or number of somatic problems, will not be presented here as these results have been separately published elsewhere for each dataset; see indicated references). The means and standard deviations for the z-transformation of each measure were calculated using the scores from all four data sets. For Physical Health, Functioning, and Mental Health Indices, z values were transformed into negative values so that greater values would indicate better adaptation.

Physical health. Physical health was assessed using six questions about the presence of specific somatic complaints in the last 4 weeks. The complaints were headache, cough, pain, fever, vomiting, and diarrhea. For instance, the child was asked "Have you had diarrhea in the last 4 weeks?" and the item was coded "yes" or "no" according to the child's answer. The outcome measure for physical health was defined as the number of "yes" answers to the question about somatic complaints.

Mental health. The UPID for children (Pynoos et al., 1998) was used for the assessment of symptoms related to PTSD. A validation of the diagnostic instrument showed a high agreement in the PTSD diagnosis (79%) between the UPID as administered by the counselors and expert interviewers (Elbert et al., 2008). The UPID allows for the assessment of symptom severity based on the frequency of symptoms reported by the child. For each single *DSM–IV* symptom of PTSD, its occurrence within the last month is scored on a scale ranging from 0 (*none of the time*) to 4 (*most of the time*). Thus, an overall trauma severity score can be calculated by summing the scores for each question that corresponds to a symptom resulting in a maximum possible score of 68. Mental health was defined as the average trauma severity score of the UPID.

Functioning. Three simple questions related to problems in functioning in different areas of children's life (social relationships, family life, and general life satisfaction) were added to the interview. For instance, with respect to social relationships, the child was asked "In the past 12 months, have you lost your interest in playing or socializing with your friends?" If the child did not understand the meaning of the question, the interviewer was instructed to help the child with further questions or examples. Impairments in psychosocial functioning were quantified as the number of "yes" answers to the three questions.

School performance. Children's performance at school was defined as the average grade achieved in four classes: mathematics, science, Tamil, and English. School grades for each child were obtained from teacher's reports about the previous school term. We did not create an index of school performance for the children of Study 3, which was conducted only a month after the tsunami. As the available reports about school grades referred to the period prior to the tsunami, the inclusion of these outcomes would not have reflected the reaction to the disaster. Therefore, z-transformation of school grades was based on the means and standard deviations of the data sets from Studies 1, 2, and 4.

Translation of Instruments

Overall, Tamil language versions of questionnaires and standardized instruments were created using translation and blind back-translation; that is, a professional counselor translated from English to the respective local language, and independent translators performed the back-translation, blind to the original version. Discrepancies were checked by experts and final versions were derived through extensive consultation with local counselors and a team of translators.

Results

Descriptive Statistics

Exposure to the war. Exposure to war-related event types was very high in all samples of Tamil children. Eighty-nine percent of the children in Study 1 and 80% of children in Study 2 reported having experienced at least one war-related life event. With respect to the children interviewed right after the tsunami, there was a clear difference between Singhalese children living in the south of the country that had hardly been affected by the civil war, and the Tamil children in Manadkaddu. Only 4.7% of the 188 Singhalese children had been affected by the war, whereas 59.2% of the 72 Tamil children reported at least one war-related life event. In the 2006 sample, this proportion was even higher, with 82.4% of the children affected by war experiences. Children in Study 1 reported an average of 2.9 (SD = 2.2) different war-related event types, and children in Study 4 reported 2.0 (SD = 1.8) types of such experiences.

Experiences of family violence. In Studies 2–4, children were asked about having experienced or witnessed violence at home. In the Vallikamam sample, 24.1% of the children reported having either experienced violence by a family member or witnessed somebody being beaten at home. In Study 3, this percentage was similarly high, with 25.4% of the children. In the Point Pedro sample, children were presented with a detailed list of family violence events of varying severity. Here, almost all children (95.6%) reported at least one aversive event happening at home. The most frequent experiences were being slapped (81.8%), being hit with an object (68.9%), and seeing a family member being hit (55.4%). Another 4.3% of children reported having experienced or witnessed at least one incident of sexual abuse or sexual violence at home. On average, children in this sample reported to have experienced or witnessed 5.3 (SD = 3.2) different violent event types in their families.

Tsunami exposure. Of the children interviewed 4 weeks after the tsunami in Study 3, 87.9% had been directly affected by the disaster. Among these children, 87.1% had to flee from the wave, 34.9% had been caught by the wave, and 65.5% had seen people struggling or dying in the water. Among the 70.9% of the children in Study 4 who were directly affected by the tsunami, these percentages were 98.6%, 22.9%, and 40.5%, respectively. On average, the tsunami severity score was 2.9 (SD = 1.2) in Sample 3 and 2.4 (SD = 1.28) in Sample 4 on a scale ranging from 1 to 5.

Multiplicity of risks. Of the 296 children of the 2006 survey, only 4 (1.4%) had not been exposed to a single risk category. Whereas a small number of children (11.1%) were found to be affected by only one risk category, the majority of children (51%) were exposed to two risk categories. One third (33.1%) of the children were affected by three risk categories, and the remaining children (3.4%) in the sample were exposed to traumatic events in all four categories.

Adaptation score. Figure 1 provides an overview on the z-transformed outcome measures and the mean adaptation score calculated for each sample. To allow for better comparison between the independent child samples, we included only data from Tamil children (n = 71) from the North-Eastern provinces of the country and left out the Singhalese children (n = 193) interviewed in Study 3. It is important to note that we had to deal with a certain amount of missing data, in particular with respect to Surveys 1, 2, and 3, stemming from our inability to send interviewers back to schools to talk to children obtain missing information. For missing data, we adopted a rather strict method of excluding the missing item as well as the related score (e.g., PTSD symptom score) from further data analysis. As a result, we could not calculate the z-transformed outcomes and the global adaptation score for all children. The percentages of children included in the regression analysis for each data set are reported in Tables 3 and 4.

As shown in Figure 1, children of the Manadkaddu sample interviewed shortly after the tsunami

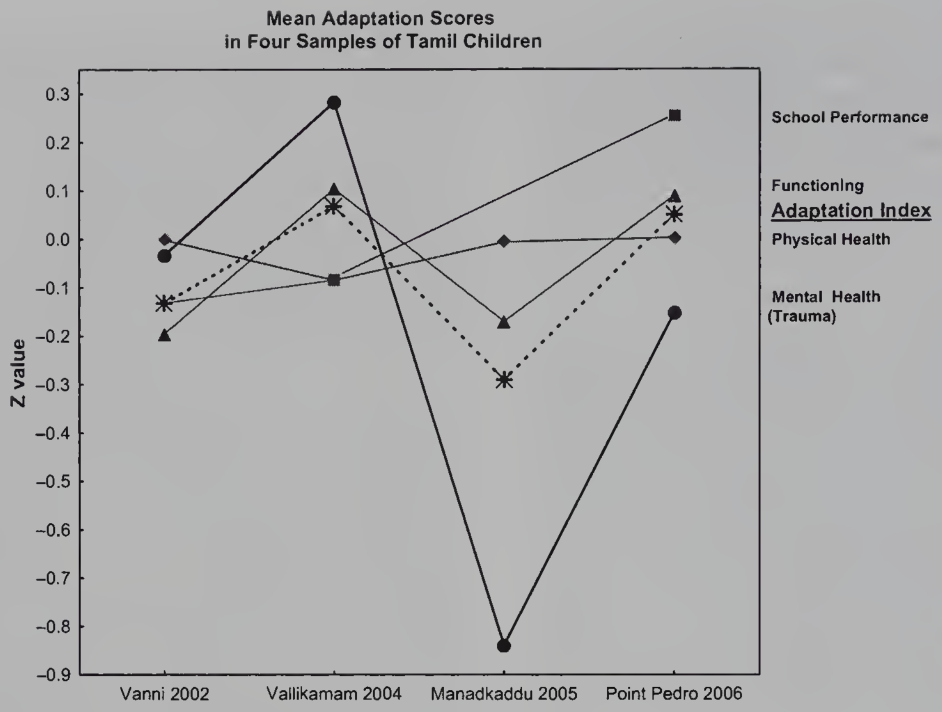

Figure 1. Plotted means of the z-transformed outcome measures (school performance, functioning, physical health, and mental health) and mean adaptation index for each dataset.

Table 3
Linear Regression Analyses on Adaptation Score (for Samples 1 and 2)

Predictor	β	*p* value	Zero-order correlation
Vanni 2002 (*N* = 270; 74% included), R^2 = .09; *F*(5, 175) = 4.57, *p* < .001			
Age	−.16	.03	−.18
Gender (male)	−.06	.37	.05
Economic status	.20	.007	.22
No. lost family members	−.08	.27	−.05
Previous exposure to war	−.17	.015	−.16
Vallikamam 2004 (*N* = 397; 84% included), R^2 = .27; *F*(10, 385) = 15.40, *p* < .0001			
Age	−.15	.001	−.19
Gender (male)	−.04	.31	.07
Loss of a parent	−.05	.23	−.08
Degree of family violence	−.26	< .0001	−.33
War experience	.06	.20	.06
Experience of a natural disaster	−.17	.0002	−.29
Physical attack (beaten or shot)	−.12	.008	−.24
Witnessing physical attack	−.21	< .0001	−.29
Having seen a dead body	−.08	.07	−.21
Experience of sexual violence	−.07	.11	−.13

showed the lowest scores with respect to mental health (trauma), functioning, and global adaptation.

Predicting Children's Adaptation

To examine potential predictors for adaptation, we calculated a linear regression model for each data set. The dependent variable is the mean adaptation score. Depending on what kind of independent variables had been assessed in the particular sample, different types and numbers of possible predictors were included for the different data sets. Results of the analyses for the two pretsunami samples are presented in Table 3, and results for the two independent samples that were assessed after the tsunami are presented in Table 4.

In the regression analysis for the 2002 study conducted in the LTTE area (Vanni), economic status and previous exposure to the war (inversely related) were the strongest predictors for children's adaptation. However, as few predictor variables were assessed in this first Sri Lankan survey, the full model only explained 9% of the variance in the adaptation index. With respect to the 2004 study, the inclusion of further traumatic events as potential predictors in the regression model resulted in 27% of variance explained. In this study, experiences of family violence, natural disaster, and physical attacks were the strongest negative predictors of adaptation. In both Studies 1 and 2, age had significant predictive power, with younger children showing higher adaptation scores.

In the regression analysis for the studies conducted after the tsunami, the severity of the natural disaster together with prior exposure to the war was among the strongest predictors of children's adaptation. In the study conducted in 2005, 1 month posttsunami, the number of lost family

Table 4

Linear Regression Analyses on "Adaptation Score" (for Posttsunami Samples 3 and 4)

Predictor	β	*p* value	Zero-order correlation
Posttsunami 2005 (*N* = 194; 74% included), R^2 = .30; *F*(10, 16) = 8.42, *p* < .0001			
Age	−.03	.65	−.22
Gender (male)	−.06	.32	−.04
No. lost family members	−.18	.008	−.33
Degree of family violence	−.10	.15	−.17
War experience	−.24	.0005	−.35
Physical attack (beaten/shot)	−.10	.13	−.16
Witnessing physical attack	−.06	.38	−.20
Having seen a dead body	−.14	.04	−.32
Experience of sexual violence	−.09	.19	−.17
Tsunami severity	−.21	.002	−.39
Point Pedro 2006 (*N* = 294; 99% included), R^2 = .26; *F*(7, 286) = 15.75, *p* < .0001			
Age	−.01	.86	−.04
Gender (male)	.05	.29	−.08
Economic status	.20	.0002	.32
No. lost family members	−.09	.07	−.09
Amount of family violence event types	−.23	< .0001	−.27
Amount of war event types	−.14	.01	−.25
Tsunami severity	−.32	< .0001	−.33

members was significantly related to a lower adaptation score in children. In the 2006 study (Study 4) where family violence and economic status were included as independent measures, the amount of violence experienced at home was inversely related to the adaptation score whereas economic status showed a strong positive relation with children's total adaptation. In both Studies 3 and 4, the regression model explained a significant amount of the variance, 30% and 26%, respectively, for each data set.

To further investigate the relation between the amount or severity of different risk factors (types of traumatic experiences related to war and family violence, tsunami severity, and loss of family members) and children's positive adaptation, we created subgroups of children from the two posttsunami surveys based on the number of stressful event types asked for in the UPID event checklist. Aversive experiences related to the war and to family violence were added up to create an indicator for the amount of traumatic experiences due to manmade violence. Figures 2a to 2c show the three different risk gradients for loss of family members, experiences of violence (war and family related), and tsunami severity. Each risk gradient demonstrates a linear negative concurrent (or dose–response) relation between risk and functioning: Exposure to more traumatic events is associated with decrements in positive adaptation.

To examine whether multiplicity of risk stands on its own as a predictor for children's adaptation, even when severity for the different risk types is taken into account, we calculated the same linear regression model for DataSet 4 except that we introduced Multiplicity Index as additional potential predictor. The result of this regression analysis is presented in Table 5.

Results of the regression indicate that the inclusion of a Multiplicity Index neither led to an increase in the variance in children's adaptation explained by the model nor significantly changed the predictive power of the variables related to the severity of single-trauma types. Instead, zero-order correlations show different pictures with both the multiplicity of risk ($r = -.21$) and severity of single trauma types (tsunami severity: $r = -.33$; severity of war exposure: $r = -.25$; amount of family violence: $r = -.27$), being significantly related to children's global adaptation toward risk.

Discussion

The data reported earlier indicate extensive exposure to general adversity and traumatic events among school-aged children in Sri Lanka, specifically Tamil children. Over the three studies that measured parental loss, more than 10% of the 8- to 16-year-old children sampled had already lost a parent. This compares with an average of 7% of the school-age population in Asia (UNAIDS, UNICEF, & USAID, 2004). Socioeconomically, these children were also far more impoverished than their developed world counterparts, with an average of 19 meals per week.

The posttsunami samples indicated that children had extensive exposure to the tidal wave, with 71%–88% of children directly affected by it (being caught or having to flee the wave, or watching people struggling or dying). Among the Tamil children, war exposure was also extremely prevalent, with 59%–89% having experienced at least one war-related life event. Frequently reported war experiences included exposure to bombings and shelling, being close to gunfire or seeing a dead body in the streets.

Relatively limited data were collected about children's experiences of family violence. However, we found an important amount of reported exposure

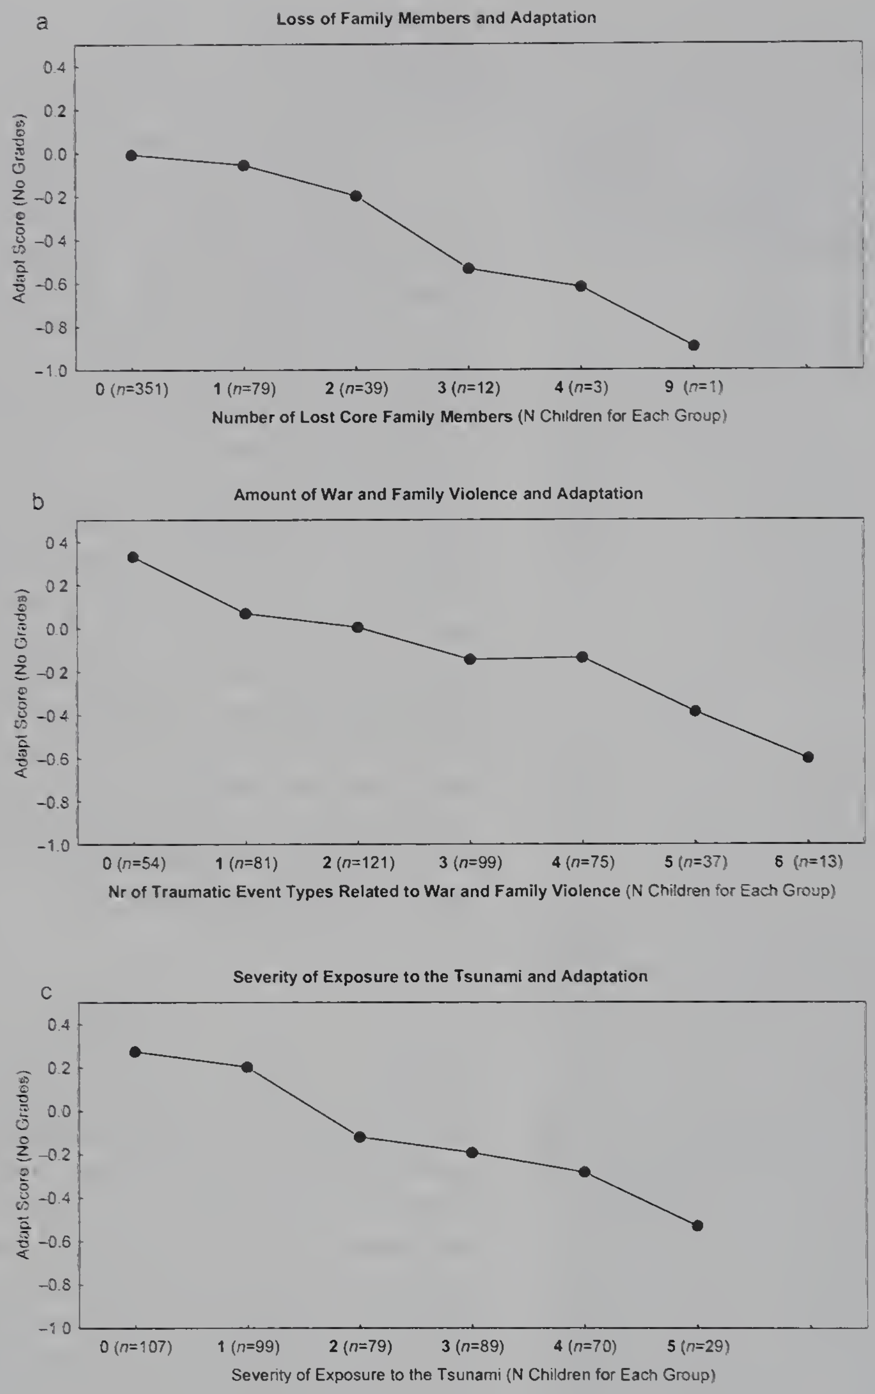

Figure 2. Risk gradients showing positive adaptation outcome for children of the two posttsunami study (Surveys 3 and 4) grouped by the (a) number of lost core family members (top), (b) number of traumatic event types related to man-made (family and war) violence (middle), and (c) severity of tsunami exposure (bottom).

to family violence across the different studies. In Studies 2 and 3, almost one fourth of children (24%–25%) reported being the victim of or witness to a potentially traumatic event related to family violence. In Study 4, where children where asked about a wide range of aversive to stressful to traumatic event types out of the family violence spectrum, 96% of the children reported to have experienced at least one such event with an average of more than five family violence event types for the whole sample. Comparing these data with the numbers of maltreatment at home reported for industrialized countries, the authors concluded that the level of family violence found in the postdisaster Tamil sample can be regarded as exceptionally high (Catani, Jacob, et al., 2008). Being faced with the frequent reports of family violence across the studies, the need for future studies that not only examine stressful and traumatic experiences that happen to children at the individual and community levels but that also include aversive influences occurring within the family becomes particularly salient to us. That would allow us to assess and capture a more holistic picture of children's adjustment (and resilience) in the aftermath of trauma, particularly in environments where the child's

Table 5

Sample 4: Predictive Power of Severity of Different Risk and Trauma Types and Multiplicity of Risks in a Linear Regression Analysis on "Adaptation Score"

Predictor	β	*p* value	Zero-order correlation
Age	−.01	.85	−.04
Gender (male)	.06	.24	−.08
Economic status	.19	< .001	.32*
No. lost family members	−.07	.15	−.09
Amount of family violence event types	−.23	< .0001	−.27*
Amount of war event types	−.13	< .05	−.25*
Tsunami severity	−.32	< .0001	−.33*
Multiplicity Index (number of risk categories)	.001	.98	−.21*

Note. $R^2 = .25$; $F(7, 286) = 13.43$, $p < .0001$.
$^*p < .05$.

bioecological context is threatened at several system levels.

Yet we are keenly aware of the challenges inherent in gathering multilevel data posttraumatic event. Even in developed nations, in addition to the lack of family-level information, relatively few data have been gathered about the details of children's trauma exposure, particularly in the acute aftermath of a disaster or other trauma events (e.g., Gewirtz & Medhanie, 2008; Walsh, 2007). In developing countries, where children's exposure to multiple stressors is much more common—whether as a result of disasters, war, or other forms of organized violence—further information is needed on the nature and extent of trauma in children's lives across systems levels, and its developmental impact.

Indeed, the extent of adversity and trauma exposure among these samples of children provides ample justification for further investigation of the impact of both individual and accumulated traumatic events on children's adjustment.

We are aware that a direct comparison between the explanatory powers of the regression analyses in the different studies is difficult given the variation in assessment and predictor variables. However, the fact that the additional inclusion of a variety of risk types in Studies 2–4 went along with a considerable increase of explained variance points to the importance of incorporating detailed assessment of prior and current traumatic stressors in addition to the stressor of interest (e.g., family violence). Our data are consistent with those in the field of developmental psychopathology (e.g., Cicchetti & Cohen, 1995, 2006; Wachs, 2000) that contend that no single factor is sufficient in explaining developmental outcomes. The risk gradients, depicted in Figures 2a to 2c, highlight the importance of considering the quantity of risk in children's adaptation in the developing world. Although we could find no studies of traumatic events per se that used this framework, our findings are similar to prior studies of stressful life events in the broader developmental literature that have indicated a relation between the number of chronic family stressors and children's adjustment (e.g., McLoyd, 1998; Shaw & Emery, 1988). In addition, however, our data also demonstrate the utility of an overall "adaptation" outcome variable that combines teacher and child report of academic, social, health, and mental health functioning. We have used the term *positive adaptation* rather than *resilience* to reflect our conceptualization of resilience as a *process* of positive adaptation (e.g., Luthar, Cicchetti, & Becker, 2000), to be captured using longitudinal data, rather than the current cross-sectional data. Follow-up data gathered over several subsequent time periods would allow for a consideration of resilience among these at-risk children in Sri Lanka.

A key advantage in modeling both cumulative risk (i.e., different trauma events, as well as life events and socioeconomic risk) and general adaptation is that, as previously discussed, such measurement allows for a broader consideration of the child's ecological context. Beyond the contribution of overall risk to adaptation, the influence of different stressors on adaptation across all samples provides some information about the power of each to disrupt children's lives. The impact of natural disasters, and the tsunami in particular, was evident throughout the studies in which exposure was assessed. Our findings of a powerful impact of the tsunami on functioning a full year after the disaster may reflect the enormous death and destruction that occurred as a result of the tidal wave, beyond the magnitude of many natural disasters (and even wars) in recent history. It may also reflect the impact of a devastating natural disaster overlaid on decades of war and civil unrest. Experiencing war violence significantly influenced adaptation across all samples, regardless of the recency of the tsunami in Study 3. (In Study 2, although the item "being in a place where war was around you" did not significantly predict adaptation, war-related proximal traumatic events did—i.e., "being beaten or shot at" and "witnessing physical violence"). Further, in two of the three studies in which it was measured (Studies 2 and 4), family violence was a highly significant predictor of adaptation. Interestingly, however, in the immediate posttsunami sample (Study 3), loss of family members eclipsed the degree of family violence experienced, in the significance of its association with positive adaptation. Further research is needed to understand predictors of adaptation in the close aftermath of a disaster, but the implication that loss of family members becomes more salient and important to children at this stage following a disaster is consistent with prior observations of ''secure base'' behavior following crises (see Pine, Costello, & Masten, 2005).

Overall, our data sets indicated that all three event types—tsunami and disaster, war, and family violence—significantly contributed to poorer child adaptation. Discrepancies between zero-order correlations and multiple correlation coefficients in the regression analyses indicate that there were suppression effects. However, given the similarity of predictors for children's adaptation found across the data sets, our data show the importance of examining the degree to which severity of exposure as well as moderating factors (within the child and context) might be more powerful contributors to adjustment than the type of trauma event. In fact, as noted earlier, the results of our analysis of both multiplicity and extent and severity of trauma events (Table 5) indicated that multiplicity (i.e., exposure to a greater number of different trauma event types) did not add unique variance to children's adaptation after accounting for severity and extent of exposure to specific trauma types (i.e., war, family violence, tsunami). Although these findings are only applicable to our sample—a sample of children in a high-risk developing country context—they do suggest the importance of further examination of how severity and extent of exposure to a specific risk class versus multiplicity (i.e., exposure to different classes of risk factors) contribute to children's adaptation.

In Studies 1 and 2, child age was also a significant contributor to positive adaptation, with younger age associated with better adaptation, even accounting for the number of trauma event types experienced. In the literature to date, findings regarding the predictive power of age for psychopathology following traumatic events are inconclusive. Whereas some studies have reported younger children to be most vulnerable for the development of trauma-related symptoms (for a discussion, see Dyregrov, Gjestad, & Raundalen, 2002), other studies have yielded different results. For example, a study of children in tsunami-affected areas in Thailand found that older age was significantly associated with depression symptoms (Thienkrua et al., 2006). In particular, studies of trauma-related mental health problems repeatedly have shown that older children are at higher risk of developing PTSD symptoms (Hadi & Llabre, 1998; Khamis, 2005; Nader, Pynoos, Fairbanks, al-Ajeel, & al-Asfour, 1993). With respect to the present data, it should be noted that the number of different event types was assessed rather than the frequency of experiencing each traumatic event. Thus, simply by virtue of their age, older children likely experienced more events within each category. Additionally, older children experienced more of the insecurity related to the civil war that has continued in Sri Lanka for over two decades.

Categorizing data across studies, it appears that in the studies that measured an array of stressors, the independent variables most significantly (negatively) associated with adaptation fall into two categories: (a) amount of exposure to trauma events and (b) loss of family support (either through death or violence). Although severity of the traumatic exposure often has been shown to be associated with compromised outcomes (e.g., Norris et al., 2002), several authors have pointed to the importance of factors within the child and his or her context (e.g., Masten & Coatsworth, 1998; Pine et al., 2005). Examining the contribution of each of these factors (i.e., event-related, or moderating factors—i.e., child and context factors) provides critical questions for further research. Pine et al. (2005) have suggested quantifying the impact of traumatic events on children according to (a) severity of exposure, (b) available family support during and following the event, (c) amount of life disruption engendered by the event, and (d) amount of social disorganization in the child's environment.

Not surprisingly, these categories also have a direct correspondence to children's bioecological micro–macro levels and additionally lend themselves to an evaluation of multiple risk and adaptation or resilience contexts. An implied category provided earlier is the importance of parent–child positive involvement and adaptive parenting practices in the aftermath of trauma (Gewitz, Forgatch, & Wieling, 2008). For example, Gewirtz et al. (2008) argue that the quality of parenting practices following mass trauma might be a key mediator in the relation between trauma exposure and child adjustment. In sum, our data hint at the importance of multiple contextual, past, and current factors in influencing children's adaptation, and point to the need for developmentally and ecologically informed longitudinal studies of children's adaptation following trauma.

Conclusions, Limitations, and Further Research

In their review of disaster research, Norris et al. (2002) report that the extant body of evidence suggests that several populations are particularly vulnerable to the impact of traumatic events: youth, survivors in developing countries, and survivors of mass violence (rather than natural disasters per se). The need for further research to understand the context of trauma in the lives of children in developing countries is clearly evident. As we have demonstrated, such data may provide a unique potential opportunity to assess the additive and interactional contributions of disasters, war, family violence, and other risks on children's development and resilience. For example, Rutter (2005) has highlighted the importance of examining the influence of both independent and nonindependent environmentally mediated risks on development. Disaster events differ from many violence-related events because they are usually nonindependent, although following the disaster event, secondary adversities emerge.

Epidemiological studies, such as the ones reported here, provide a first step in understanding the nature of exposure to traumatic events and adversity on children's adaptation in the developing world. Providing representative sample sizes and population-based data, these studies provide a broad baseline ''snapshot'' of the impact of a variety of traumatic stressors on children's adaptation. In this study, most of the outcome measures used to define positive adaptation refer to the absence of physical or psychological pathology. This is in agreement with Luthar et al. (2000) who have noted: ''The optimal outcome indicators are those that are conceptually most relevant to the risk encountered, so that when there are serious life adversities such as exposure to war, the absence of psychiatric distress can be a more logical outcome than excellence in functioning at school'' (p. 858). Nevertheless, future studies could use broader multi-informant, multimethod measures of adaptation that do not rely solely on the absence of pathology but that incorporate positive, developmentally appropriate domains, such as social competence (e.g., Masten, 2001; Masten et al., 1999).

Moreover, the use of multi-informant data provides added external validity (Rutter, 2005). In situations in which political instability or other factors preclude or limit the capacity for ongoing research, cross-sectional, epidemiological data provide value in understanding the context of risk and protection, and external validity can be maximized by using more than one informant source. The major limitation of this study, however, is its lack of longitudinal data, which precludes the possibility of understanding and disentangling either the sequential effects of different traumatic experiences or the unfolding of their developmental impact.

Pynoos et al. (1999) have proposed a developmental psychopathology model of traumatic stress that places traumatic exposure in the emerging developmental context. As children age, new experiences create opportunities for traumatic reminders, secondary adversities, and new methods for positive adaptation. Further traumatic experiences create potential vulnerabilities that may erode or compromise prior adaptation. In addition to the common observation that age factors intersect with traumatic exposure (i.e., older children have experienced more trauma), developmental factors also interact with factors in the ecological context (e.g., family, school, community, etc.) to enhance protection or vulnerability to adaptation. In addition, studies that have gathered data on different types of traumatic exposure—within and beyond the family—have indicated the interdependence of different traumatic experiences (Landau, 2007; Lynch & Cicchetti, 1998; Walsh, 2007).

Many research questions remain to be answered regarding the impact of trauma on children in the developing world, with its higher base rate of adverse and traumatic events. A developmental risk and protection model framed within a bioecological framework provides a unique opportunity to investigate children's lives in such contexts and might provide invaluable insights into the intersecting role and impact of various system levels in children's overall adjustment posttrauma. Finally, the special value of this research lies in its potential to build a foundation for the development and evaluation of cross-contextual interventions to enhance protective processes for traumatized children in developing countries.

Growing Pains: The Impact of Disaster-Related and Daily Stressors on the Psychological and Psychosocial Functioning of Youth in Sri Lanka

Gaithri A. Fernando
California State University, Los Angeles

Kenneth E. Miller
Harvard School of Public Health

Dale E. Berger
Claremont Graduate University

Daily stressors may mediate the relation between exposure to disaster-related stressors and psychological and psychosocial distress among youth in disaster-affected countries. A sample of 427 Sri Lankan Sinhalese, Tamil, and Muslim youth (mean age = 14.5) completed a survey with measures of exposure to disaster-related stressors and daily stressors, psychological distress (posttraumatic stress, depression, and anxiety), and psychosocial distress. The results indicated that daily stressors significantly mediated relations between war- and tsunami-related stressors and psychological and psychosocial distress. Some daily stressors not directly related to disaster also predicted functioning. These results point to the need for policies and interventions that focus on reducing proximal daily stressors that are salient to Sri Lankan youth exposed to disasters.

It is by now a basic tenet of developmental psychology, supported by nearly four decades of research, that children's development is influenced by numerous factors at multiple levels, ranging from intrapersonal variables, both biological and psychological, to factors operating at the level of the family, community, and society (Bronfenbrenner & Morris, 1998; Cooper & Guthrie, 2007). This ecological or multilevel framework, though originally applied to the study of typical or healthy development, is also used to examine psychopathology as well as resilience of youth living in high-stress environments (Buckner, Bassuk, & Beardslee, 2004; Fitzgerald, Karraker, & Luster, 2002; Masten, 2006; Pynoos, Steinberg, & Piacentini, 1999). In their efforts to understand the impact of stressful events and contexts such as parental divorce and poverty on children's emotional, cognitive, and social well-being, researchers have increasingly transcended the earlier emphasis on simple main effects models, looking instead to identify and understand mediating and moderating factors at multiple levels of influence that might explain or influence the relation between stressors and children's mental health (Cicchetti & Lynch, 1993; Osofsky, 2004; Pynoos et al., 1999). The adoption of an ecological framework and the development of risk or causal models that specify mediating and moderating variables at multiple levels of children's social and material ecologies have, in turn, facilitated the development of empirically based interventions that target those variables most amenable to change.

Research on the physical and mental health of children and youth living in settings of armed conflict and natural disaster, or what the Interagency Standing Committee (IASC) has termed *emergency settings* (IASC, 2007), has lagged somewhat in this shift toward an ecological perspective. This lag appears to be related to two major issues. First is the issue of which predictors are, or ought to be, the focus of study. Second is the issue of which outcomes are, or ought to be, the focus of measurement.

This study was made possible by funding from Pomona College, a grant from the Minority Biomedical Research Support program 1R25 GM61331, at California State University, Los Angeles, and by material support from the Centre for Psychosocial Care, Sri Lanka. The authors wish to thank Mr. Jagath Ranawake and the counselors at the Centre for Psychosocial Care and community leaders, teachers, and parents in Ampara who helped with this study. Thanks also to Paul Bolton, who provided important feedback on an earlier version of this article.

Issues Related to Children and Youth Exposed to Disasters

Several reviews synthesize the findings on predictors of mental health in children exposed to situations of armed conflict (Barenbaum, Ruchkin, & Schwab-Stone, 2004; Belfer, 2006; Fazel, Wheeler, & Danesh, 2005; Kalksma-Van Lith, 2007; Stichick, 2001). The reviews demonstrate that the primary focus remains the documentation of the simple or direct relation between exposure to experiences of violence and loss (e.g., exposure to gunfire and bombs, the violent death of family members) and children's mental health. The underlying assumption is that direct exposure to potentially traumatic disaster-related events represents the major threat to children's mental health in emergency settings. Consistent with that assumption, numerous studies have documented a positive—though highly variable—correlation between severity of exposure to war and other disaster-related stressors and psychiatric symptomatology in children, particularly symptoms of posttraumatic stress disorder (PTSD; American Psychiatric Association, 2000; see, e.g., Fazel et al., 2005; Macksoud & Aber, 1996; Neuner, Schauer, Catani, Ruf, & Elbert, 2006; Qouta, Punamäki, & El Sarraj, 2003; Thabet & Vostanis, 2000). This emphasis on the traumatic impact of direct exposure to war- and disaster-related stressors has led to numerous calls for trauma-focused interventions aimed at ameliorating symptoms of PTSD in children living in emergency settings (e.g., Neuner et al., 2006; Yule, 2002).

There is, however, increasing interest in more contextualized approaches that consider multilevel influences on the relation between disasters and children's mental health (Cairns & Dawes, 1996; Dawes & Donald, 1994; Garbarino & Kostelny, 1996; Hart, Galappatti, Boyden, & Armstrong, 2007; Heptinstall, Sethna, & Taylor, 2004; Miller & Rasco, 2004). A growing body of evidence suggests that stressful social and material conditions caused or exacerbated by armed conflict and natural disasters may predict mental health status as well as, or better than, actual degree of exposure to war or to other disaster-related events (Al-Krenawi, Lev-Wiesel, & Sehwail, 2007; Miller, Omidian, Rasmussen, Yaqubi, & Daudzai, 2008; Wessells & Monteiro, 2006). War and natural disasters do a great deal more than expose young people to potentially traumatic stressors; they also generate a host of enduring, stressful conditions of daily life. For the purposes of this study we use the term *daily stressors* to refer to these stressful conditions that may impinge upon children's psychosocial well-being. Such conditions can arise from any area of a child's ecology and include poverty caused or worsened by the loss of family livelihoods, displacement into crowded and impoverished refugee camps with a corresponding loss of privacy and autonomy, a loss of social support caused by the weakening of social networks through the death of family members, alterations in family structure or functioning when family members are killed or disabled, and a lack of access to basic goods and services such as health care and schooling (Barenbaum et al., 2004; Kalksma-Van Lith, 2007; Miller & Rasco, 2004; Wessells & Monteiro, 2006).

Although daily stressors such as those listed earlier may function to mediate or explain the impact of war and other disasters on children's mental health, it seems reasonable to assume that even in situations of complex emergency, some children will also be affected by stressors that may also occur in nonemergency settings, such as family violence and sexual abuse. To the extent that such stressors are unrelated to conditions of war or disaster, they essentially function as independent sources of daily stress in children's lives. This raises the important possibility that, even in emergency settings, at least some of the variance in psychological functioning (including such disaster-related psychiatric conditions as PTSD) may be due to sources of traumatic stress unrelated to conflict or disaster. Thus, one purpose of this study is to examine the relations between direct exposure to war- and tsunami-related stressors, exposure to daily stressors, and distress in children exposed to such stressors.

Issues Relating to Assessment of Outcomes in Children Exposed to Disasters

There is robust research indicating that reactions to trauma in children look qualitatively different from adult reactions to traumatic events (Davis & Siegel, 2005; Osofsky, 2004; Shaw, 2000). However, although researchers acknowledge the developmental and age differences in how children may express trauma reactions, less attention has been paid to cultural differences in such processes. Most studies of children's distress and well-being in complex emergencies have conceptualized these constructs using Western psychiatric diagnoses and self-report measures developed and standardized on Western populations. The most common outcomes examined are depression, anxiety, and child PTSD (for reviews and critiques of this method, see

Barenbaum et al., 2004; Hollifield et al., 2002; Miller, Kulkarni, & Kushner, 2006). Assessments of trauma reactions in children have generally focused on emotional and cognitive symptoms of distress (internal or intrapsychic experiences) while largely overlooking the dimension of psychosocial functioning (internal experiences that affect external, culturally appropriate behaviors). Although a majority of armed conflicts and major natural disasters in the past 50 years have occurred in non-Western nations (UNICEF, 2008; United States Committee for Refugees, 2009), by 2001, only about 14% of samples in disaster research have been from these countries (Norris et al., 2002). When such studies have been conducted, surprisingly little attention has been paid to cultural variations in the ways in which children's well-being and distress are expressed and understood within local cultures.

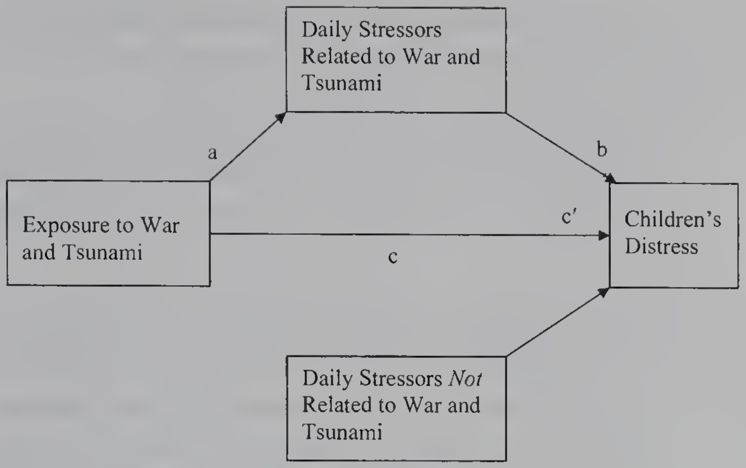
An understanding of children's functioning that takes social domains into account is particularly salient to collectivistic cultures, where general functioning is dependent on social networks, religious beliefs, cultural practices, and social roles (Summerfield, 1999; Triandis, 1995). Thus, culturally sound assessments of psychosocial functioning merit considerable attention in research conducted with children living in settings of complex emergency. The second goal of the current study was to address this empirical gap. Using a culturally specific measure of children's psychosocial status along with intrapsychic measures of distress, we examined the relations between war and tsunami exposure, daily stressors, and psychological and psychosocial functioning in Sri Lankan youth.

A Contextual Model: Looking Beyond Catastrophic Stressors

Current treatment programs designed to alleviate psychiatric symptoms among children who are exposed to war or natural disasters often focus solely on exposure to the disasters themselves. This emphasis may be overly narrow if in fact, significant variance in children's distress and development is explained by daily stressors caused and exacerbated by, or even unrelated to conflict or natural disaster. Moreover, to the extent that some daily stressors mediate the impact of war or natural disaster on psychosocial functioning and development, it may be especially productive to focus intervention efforts on altering those stressors. War- and other disaster-related traumatic stressors are events that cannot be altered, although their residual impact on psychosocial well-being may be alleviated, but daily stressors represent ongoing, proximal events or situations that continue to adversely affect children, and can be altered.

Few studies have assessed the impact of daily stressors on children's mental health in emergency settings. However, research with adults in zones of ongoing conflict has shown a consistent pattern where the strength of the relation between direct exposure to war and mental health drops considerably when daily stressors are taken into account. Indeed, daily stressors have been demonstrated to account for greater variance in some mental health outcomes, compared with direct exposure to war experiences. For example, among adult refugees from Darfur living in Chadian refugee camps, stressors associated with daily life in the camps such as difficulty accessing basic resources and safety concerns predicted levels of PTSD, as well as indigenous idioms of distress, better than previous exposure to the genocidal violence in Darfur (Rasmussen et al., 2010). Similarly, in a study of adults in Afghanistan, daily stressors such as poverty, unemployment, domestic violence, and social isolation predicted psychological and psychosocial distress better than previous exposure to war-related violence and loss; moreover, daily stressors and war exposure accounted for roughly equal variance in levels of PTSD symptoms (Miller et al., 2009).

In one of the few studies of children that examined the impact of daily stressors in a zone of ongoing conflict, Al-Krenawi et al. (2007) found that family violence was more strongly related to children's mental health than the degree of exposure to political violence. Using ethnographic methods to study families in Afghanistan, de Berry et al. (2003) found that in addition to war-related violence and loss, parents and children identified family violence, poverty, and lack of access to education as major sources of childhood stress. Hart et al. (2007) similarly used a variety of qualitative methods with children in a heavily war-affected region of Sri Lanka, where children identified aspects of armed conflict as well as other threats to their well-being such as poisonous snakebite, theft, and flooding as significant sources of threat to their well-being. Unfortunately, when considering children's mental health in settings of complex emergency, few other studies have looked beyond children's direct exposure to war- or disaster-related traumatic stressors. Consequently, data remain sparse on the relation of daily stressors to the mental health of children living in war- and disaster-affected areas.



Daily Stressors Related to War and Tsunami

Children's Distress
Daily Stressors *Not* Related to War and Tsunami

Figure 1. Model for assessing mediation in the relation between disaster exposure, daily stressors, and children's distress.

Figure 1 depicts the hypothesized relation between disasters such as war and daily stressors, and emotional, cognitive, and social distress in youth. In the model, exposure to war and natural disasters exerts a direct effect on distress; however, the influence of this exposure is partially mediated by a subset of daily stressors caused or exacerbated by the conditions of war or natural disaster. There is also a subset of daily stressors that influence children's distress independently of any relation to war and natural disaster. We have intentionally not specified the particular daily stressor(s) in each box (mediators and nonmediators) of the model. Given the current paucity of findings in this area, it seemed premature to specify the relation of particular daily stressors to disasters, on the one hand, and children's distress, on the other. The model in Figure 1 was tested with youth living in a heavily war-torn and tsunami-affected district in eastern Sri Lanka.

Background: Sri Lanka. The island of Sri Lanka has a population of just over 20 million, over 75% of whom are Sinhalese Buddhists. Significant minority ethnic groups include Tamils and Moors, commonly referred to as Muslims (Department of Census and Statistics, Sri Lanka, 2001). Sri Lankans tend to be collectivistic and traditional in orientation (Durvasula & Mylvaganam, 1994; Fernando, 2005, 2008). However, the long-drawn-out armed conflict that began in the 1980s and the tsunami of 2004 appear to have disrupted the social bonds that tie children to parents and families to each other. Somasundaram (2003) has referred to this type of disruption as "collective trauma," a condition where whole communities are so impacted by violence and loss that the very fabric of society is destroyed, exposing people to multiple traumatic events with few safety nets against resulting trauma. Children, being most dependent on their parents and supportive sociocultural structures, are the most likely to be affected by collective trauma. Additionally, children are directly affected by the armed conflict: kidnapped to become child soldiers, being detained and tortured, becoming crippled due to mine explosions, and/or orphaned (Amnesty International, 2009; South Asia Free Media Association [SAFMA], 2008).

A brief respite from the war began in 2002 after a cease-fire agreement was signed by both parties. However on December 24, 2004, just as Sri Lankans were beginning to look forward to rebuilding their lives, the tsunami crashed into Southeast Asia, killing over 35,000 and displacing over a million (SAFMA, 2008). Currently, thousands of families still live in barren, impoverished refugee camps. In addition, the Tamil militants returned to armed conflict in 2005, ironically citing a perceived lack of fairness in the distribution and disbursement of tsunami relief funds as the reason for their return to militancy (SAFMA, 2008). In 2008, over 450,000 people were considered to be living as internally displaced people or refugees due to both the war and the tsunami (SAFMA, 2008).

The Ampara district, where the present study was conducted, is one of the regions most severely affected by the tsunami, with more than 10,000 killed and many more displaced from their homes (Canadian International Development Agency [CIDA], 2009; Department of Census and Statistics, Sri Lanka, 2005). Ampara also represents the eastern frontline of the civil war and was the site of numerous war-related atrocities (Amnesty International, 2008). Many villages, known as "border villages," lie on the border between territories disputed between the Sri Lankan government and the Tamil militants; villagers in these areas often found themselves in the midst of fierce fighting between the two military forces. It is against this background that this study was conducted with Sri Lankan youth.

Issues of age, gender, and ethnic group membership. Few consistent results have been established on the relation between demographic variables (age, gender, and race), disaster exposure, and outcomes for children living in disaster settings. Some studies have found that younger age is a predictor of worse functioning (Bonanno, 2008), whereas others have found no relation between age, exposure, and outcome (for a review and meta-analysis, see Evans, Davies, & DiLillo, 2008). In terms of gender, a robust finding is that girls tend to internalize distress (as depression or anxiety) whereas boys tend to externalize it (as aggressive behaviors) (Evans et al., 2008). A prior study conducted with children in the western and northern parts of Sri Lanka revealed that whereas gender did not significantly predict distress, younger age did (Fernando & Makanui, 2005). The same study found that Muslim and Christian children reported worse psychosocial outcomes, whereas Buddhist and Hindu children reported less distress (Fernando & Makanui, 2005). Because this earlier study was conducted in a different region of Sri Lanka, we will make no predictions in this study as to which demographic variables might be related to predictors and outcomes.

The current study has several goals: (a) to examine the relation of war- and tsunami-related stressors to the psychological and psychosocial functioning of Sri Lankan youth, (b) to examine whether daily stressors mediate this relationship, and (c) to determine which demographic characteristics might be related to distress in Sri Lankan youth. Several hypotheses were tested in this study (see Figure 1); these hypotheses are listed in groups based on the analysis being conducted.

1. War and tsunami exposure will be significantly related to daily stressors (pathway a).
2. War and tsunami exposure will be significantly related to psychological and psychosocial outcomes for Sri Lankan youth (pathway c in Figure 1):
   a. War and tsunami exposure will be significantly related to PTSD, depression, and anxiety.
   b. War and tsunami exposure will be significantly related to overall psychosocial status and to internalizing, externalizing, and psychosocial withdrawal components of psychosocial status.
3. Controlling for the effects of war and tsunami exposure, exposure to daily stressors will be significantly related to psychological and psychosocial outcomes (pathway b):
   a. Exposure to daily stressors will be significantly related to PTSD, depression, and anxiety, after controlling for the effects of war and tsunami exposure; and
   b. After controlling for the effects of war and tsunami exposure, exposure to daily stressors will be significantly related to overall psychosocial status and to internalizing, externalizing, and psychosocial withdrawal components of psychosocial status.
4. Daily stressors will mediate the relation between exposure to the war and tsunami and all outcome measures (pathway c′; weaker than pathway c in Figure 1):
   a. The relation between war and tsunami exposure and the outcomes of PTSD, depression, and anxiety will be weaker after including daily stressors to the model;
   b. Similarly, adding daily stressors to the model will weaken the relation between war and tsunami exposure and overall psychosocial status, and to internalizing, externalizing, and psychosocial withdrawal components of psychosocial status.

If exposure to daily stressors does in fact serve as a mediator in the model, then the regression weight for exposure to war and tsunami predicting outcomes will be smaller when the mediator is also in the model (pathway c′ in Figure 1) than when the mediator is not in the model (pathway c). With full mediation, pathway c′ would be zero. Because no prior studies have considered this model, no prediction was made as to whether daily stressors would fully or partially mediate the relation.

We also examined whether age, gender, and ethnicity are significantly related to disaster exposure, daily stressors, and the outcomes of interest. No hypotheses about these relations were formulated, however, given that prior research has not established such relationships among Sri Lankan youth.

Method

Participants

Participants for this study comprised three groups of students: Sinhalese (n = 223; girls = 108), Tamil (n = 89; girls = 53), and Muslim (n = 115; girls = 79). Student grades ranged from 7 to 13 (Advanced Level II, equivalent to high school senior). Approximately half the sample was female (56%; n = 240). The mean age of the youth was 14.5 years (SD = 1.88), with a range of 11–20 years; no significant differences were found for age by ethnic group. Religious affiliation was exclusively related to ethnicity for the Sinhalese and Moor students (Buddhist and Muslim, respectively). Among the Tamil students, 54 were Hindu whereas 35 were Christian. Most participants' families (97%) could be classified as being of lower socioeconomic status (relative to other Sri Lankans) based on parental income, education, and profession.

Instruments

Demographic survey. The survey included questions about the respondent's gender, age, and education, as well as questions about parental education, income, and profession, type of household (intact, extended families living in the home), type of housing (permanent housing vs. temporary shelter), and religiosity (importance of religious beliefs, frequency of practicing religious beliefs).

The Sri Lankan Index of Psychosocial Status for Children (SLIPSS–C). The SLIPSS–C is a 49-item measure assessing multiple subdomains of psychosocial distress. The measure was developed in Sinhalese and Tamil languages using qualitative methods, including focus groups with children. A more extensive discussion of the development and validation of the measure is available elsewhere (Fernando, Miller, Uyanavithanage, Prasad, & Garcia, 2008). Respondents endorsed items assessing the frequency of feelings and behaviors, from 0 (*never*) to 4 (*almost always*), with higher scores reflecting more psychosocial distress. Internal consistency of the measure was high (Cronbach's alpha = .85) and validity of the scale for Sri Lankan youth has been established (Fernando et al., 2008). Exploratory factor analysis for 46 items using principal axis extraction and direct oblimin (oblique) rotation yielded three factors with eigenvalues > 1.0: internalizing or intrapsychic symptoms (20 items, alpha = .83; e.g., feeling sad, angry, lonely; labeled *S-Internalizing*), externalizing behavior (15 items, alpha = .79; e.g., fighting with friends and neighbors; labeled *S-Externalizing*), and psychosocial withdrawal (11 items, alpha = .65; e.g., difficulty talking to parents and other adults; problems with performing one's rituals and duties; labeled *S-Withdrawal*). The internal consistency of the last subscale is somewhat lower than the others but still considered acceptable (Oyserman, Coon, & Kemmelmeier, 2002). The impact of different types of stressors on the participants' psychosocial status in these three distinct subdomains was examined.

War- and Tsunami-Related Stressor Scale (WTSS). The WTSS is a 12-item scale assessing frequency of exposure from 0 (*never*) to 2 (*more than once*) to various potentially traumatic war-related events (e.g., bomb blasts, kidnappings, shootings) and tsunami-related events (e.g., experiencing the tsunami waves, seeing people die due to the tsunami). Items were selected in consultation with a local team of counselors and based on data from focus groups recruited to develop the SLIPSS–C. Internal consistency (Cronbach's alpha) of the WTSS was .72, although internal consistency may not provide an adequate measure of reliability for this scale (see Netland, 2005). Cronbach's alpha is likely to underestimate reliability for scales where many different experiences are relevant, yet individual items are not necessarily expected to correlate highly. Additionally, although we recognize that any one war- or tsunami-related stressor can have potentially devastating effects, a summative score on the WTSS was used in these analyses. A higher score on the WTSS indicates exposure to multiple war- and tsunami-related events.

Children's Daily Stressor Scale (CDSS). The CDSS includes 20 items generated from focus group transcripts obtained during the development and validation of the SLIPSS–C. The items were based on the most frequent responses to questions posed to focus group participants about stressors they most commonly encountered while living amid poverty, war, and natural disasters. For each item, participants were asked to indicate whether they experienced that event, from 0 (*never*) to 2 (*more than once*). Further details on the development of this measure are provided elsewhere (Miller, Fernando, & Berger, 2009; Miller, Fernando, Uyanavithanage, Prasad, & Ranawake, 2008). Internal consistency (Cronbach's alpha) of the scale was .75. Principal axis extraction and direct oblimin (oblique) rotation revealed three factors, each assessing a subdomain of daily stressors. The first subscale was labeled Deprivation, measured by 10 items (e.g., "Lack of clean drinking water"; alpha = .71). The second subscale was labeled Interparental Conflict, measured by four items (e.g., "Seen your mother or father hitting your father or mother"; alpha = .66). The third subscale was labeled Abuse, measured by six items (e.g., "Been beaten so hard you had injuries"; alpha = .62). The total CDSS score and scores on each of the three subscales were used to examine the contribution of daily stressors to psychosocial status as well as the putative mediating role of these stressors in the relation of war and tsunami exposure to psychosocial status.

Child Posttraumatic Stress Scale (CPSS). The CPSS is a 17-item checklist scale assessing the frequency of symptoms of posttraumatic stress in children exposed to a traumatic event, from 0 (*not at all*) to 3 (*almost always*; Foa, Johnson, Feeny, &

Treadwell, 2001). The CPSS has been used reliably in several studies of children exposed to traumatic stressors (Hawkins & Radcliffe, 2006). Internal consistency of the measure was high (Cronbach's alpha = .81). Respondents were asked to think about the most fearful event they had experienced and to indicate whether, in the past 2 weeks, they experienced any of the feelings, thoughts, or behaviors listed relating to the event they experienced. Higher scores reflect higher levels of PTSD symptomatology.

The Birleson Depression Self-Rating Scale (DSRS). The DSRS is an 18-item scale assessing the frequency of symptoms relating to depression on a scale ranging from 0 (*never*) to 3 (*almost always*; Birleson, Hudson, Grey-Buchanan, & Wolff, 1987). The scale has demonstrated acceptable psychometric properties in studies with children (Myers & Winters, 2002). In the current study, three items were dropped due to poor item–total correlations for this sample, yielding a 15-item scale (Cronbach's alpha = .70).

The Multidimensional Anxiety Scale for Children (MASC). The MASC is a 41-item scale assessing the frequency of symptoms relating to anxiety in children on a frequency scale ranging from 0 (*never*) to 3 (*almost always*; March, Parker, Sullivan, Stallings, & Conners, 1997). A 14-item brief version of the scale was used in this study (Cronbach's alpha = .73).

Note on validity and translation of measures, and terminology The PTSD (CPSS) and depression (DSRS) scales have not been validated for use with Sri Lankan children. Therefore, care was taken during translation and back-translation to ensure equivalency of meaning, comprehensibility, and acceptability to the children (P. Bolton, personal communication, June 5, 2008). The measures were translated into Sinhalese and Tamil by the research team in consultation with the authors. The measures were then back-translated by a Sinhalese psychologist and a Tamil language professor to ensure equivalence of meaning. For ease of communicating results, the CPSS, DSRS, and MASC scales are referred to as PTSD, Depression, and Anxiety scales, respectively, hereafter.

Procedure: Recruitment of Respondents and Administration of Survey

The study was conducted in accordance with the ethical principles detailed by the American Psychological Association and recommendations for disaster research (Kilpatrick, 2004), and was approved by the Institutional Review Board at the first author's institution.

A decision was made by the research team to attempt to recruit youth through the school system because despite the environmental hazards and difficulties, Sri Lankan parents still value education, and ensure that their children attend school regularly. Therefore, school-based samples are representative of the rural population of children in Sri Lanka. Additionally, a decision was made early on to oversample from the ethnic minority groups. Although Sinhalese comprise over 75% of the population of Sri Lanka (Department of Census and Statistics, Sri Lanka, 2001), we oversampled Tamil and Muslim children so that within-group comparisons as well as between-group comparisons could be made. An attempt was made to try to recruit children and youth from late childhood to late adolescence, so that although a broad developmental spectrum could be represented, children would be old enough to understand the questions on the survey without direct intervention by teachers or parents.

The authors worked though a local nongovernmental organization where several counselors represented each ethnic group (Sinhalese, Tamil, and Muslim). Six counselors were trained as research assistants and aided in recruitment, conducting focus groups and discussion groups, writing the scales in comprehensible Sinhalese and Tamil, and administering the surveys. Four schools (two Sinhalese, one Tamil, and one Muslim) were selected for administration of the survey because of their location and the probability of including children in the school who were exposed to the war, the tsunami, or both.

Fully informed written consent was obtained from parents and assent from children prior to administration of the survey. Data were gathered over 4 consecutive days, with the administration of the survey to one school on each day. Children followed along with the survey administrator as each item on the survey was read. All phases of the administration were supervised to assure standardization. The surveys took approximately 1.5 hr (with breaks) to administer to children in Grades 6–8, and less than an hour to administer to children in the upper grades. When the entire administration was completed, children were provided and read a ''Debriefing Form'' and given an opportunity to provide feedback about the experience of having taken the survey. As a token of appreciation, all children were given a package of basic school supplies and a piece of candy, though these had not been promised to the children, to avoid coercion. Finally, each school received a small but needed item identified by the principal, valued at Sri Lankan Rs. 10,000 (approximately US$100).

Of the 537 surveys available for this study, lack of consent forms led to 16 dropped surveys and another 94 were dropped because of questions about the validity of the data (the SLIPSS–C included three validity checks; Fernando et al., 2008). Cases with data missing on any of the variables used in the mediation analyses were also dropped, leaving 427 cases for the current analyses. Analyses of surveys with missing data did not show significant differences in age, gender, or ethnicity between the group remaining in the study and the group dropped from further analyses.

Notes on analyses. Because we conducted numerous analyses, an alpha level of .001 was used as the general criterion for statistical significance, although alpha values of .01 and .05 are shown to reveal patterns in the results. Effect sizes are shown as correlations, as beta weights, as R^2 added in regression analyses, and as group means with standard deviations for group comparisons. We report item means rather than the mean of total scores on the various scales to facilitate interpretations relative to the scale anchors and enable comparisons of scales that use the same anchors but have differing numbers of items (e.g., the CDSS has 20 items and the WTSS has 12 items, but both use 0–2 scale anchors). Nonparametric tests are reported in some cases where distributional assumptions of parametric tests are not met and nonparametric tests fail to support the parametric results. Although the sample size is $n = 427$ for all analyses that use all groups, the degrees of freedom for t tests vary because we used the test that does not assume equal variances.

Results

Analyses

Several analyses were conducted in accordance with the hypotheses and the exploratory examinations mentioned earlier. First, we examined whether age, gender, or ethnicity were significantly related to exposure to disaster-related and daily stressors. Second, we examined whether the outcomes of posttraumatic stress, depression, anxiety, and psychosocial status differed by age, gender, or ethnicity.

Next, we tested each of the hypotheses listed earlier in this study. Correlation and regression analyses were conducted in the following manner:

1. To test our first hypothesis, that exposure to disaster-related stressors was significantly related to daily stressors, a correlational analysis was conducted between WTSS scores and CDSS scores.
2. To test the second set of hypotheses that exposure to the war or tsunami will predict psychological and psychosocial outcomes, simple regressions were conducted with WTSS scores as the only predictor for each of the measured outcomes (PTSD, Depression, Anxiety, SLIPSS–C, S-Internalizing, S-Externalizing, and S-Withdrawal).
3. To test the third set of hypotheses, that exposure to daily stressors in general would predict psychological and psychosocial outcomes after accounting for exposure to disaster-related stressors, total CDSS scores were added as a second step in multiple regression analyses for each of the outcomes.
4. To test the fourth set of hypotheses, that exposure to daily stressors will mediate the relation between exposure to disaster-related stressors and outcomes, the regression weights in each model were examined. If the beta weight for WTSS obtained in the first step of each model is reduced when CDSS is entered into the model, mediation is demonstrated.
    a. To examine whether specific types of daily stressors mediated the relation between disaster-related stressors and outcomes, each of the three subscale scores of the CDSS were entered at the second step of each of the multiple regression models. Because three conceptually distinct factors emerged from factor-analyzing the CDSS, separate mediation analyses were conducted using the Deprivation, Interparental Conflict, and Abuse subscales of the CDSS.
    b. Finally, demographic variables were entered into each of the six models, to assess whether any of these variables would further clarify the relation between the predictors and outcomes. As noted earlier this was an exploratory analysis because there are no robust data on which to build hypotheses on such variables as age, gender, and ethnic group membership in this sample.

The results of these analyses are presented as follows.

Demographic Comparisons

Table 1 provides information on age, gender, and ethnicity for exposure to stressors using the mean of the item scores as the reported statistic. The differences are reported for each group along with an indication of statistical significance ($p < .001$) for pairwise group differences using t tests not assuming equal variances. Examination of the relation between age and stress exposure revealed that age was not significantly related to WTSS scores, $r(427) = .04$, *ns*, but was positively related to CDSS scores, $r(427) = .23$, $p < .001$. This relation was particularly strong for the Deprivation scale of the CDSS, with older children reporting greater deprivation, $r(427) = .33$, $p < .001$. Gender differences were not significant for WTSS or overall CDSS scores.

Examining ethnic group differences in exposure to stressors revealed that Tamil and Muslim youth obtained significantly higher mean WTSS scores (indicating greater exposure to multiple war- and tsunami-related stressors) compared to Sinhalese youth. The three groups did not differ significantly on CDSS (daily stressors) total scores. However, the groups did differ on the subscales of the CDSS. Compared to the Sinhalese youth, Muslim and Tamil youth obtained significantly higher mean Deprivation scores. Muslim youth obtained a significantly higher mean Abuse score but a significantly lower Interparental Conflict score, compared to Sinhalese and Tamil youth.

Table 2 provides information on the relation between demographic variables and outcome measures. Age was not significantly related to any of the outcome measures. Significant gender differences were obtained for two subscales of the SLIPSS–C; boys obtained significantly higher S-Externalizing scores, $t(376) = 4.56$, $p < .001$ ($d' = .45$), whereas girls obtained significantly higher S-Internalizing scores, $t(418) = 3.76$, $p < .001$ ($d' = .36$). Examination of scores obtained by ethnic groups revealed that Tamil and Muslim youth obtained significantly higher mean SLIPSS–C scores compared to Sinhalese youth. Subscale analysis revealed an especially strong ethnic group difference on S-Internalizing, with Muslim youth obtaining the highest mean score, Sinhalese youth obtaining the lowest, and Tamil youth scoring between these two groups (all pairwise differences significant at $p < .001$).

Other outcome measures also revealed significant ethnic group differences. Tamil and Muslim youth obtained significantly higher mean Depression scores compared to Sinhalese youth, and Muslim youth obtained a significantly higher mean Anxiety score compared to Sinhalese and Tamil youth. The ethnic groups did not differ significantly on PTSD. Overall, psychological and psychosocial outcomes appear to be worst for Muslim youth, whereas Sinhalese youth reported the least amount of distress. Tamil youth fell somewhere between these two groups. The relation of the demographic variables of gender, ethnicity, and age to outcome

measures will be examined in subsequent regression analyses.

The Relation Between War- and Tsunami-Related Stressors and Daily Stressors

A simple correlation analysis indicated a significant relation between WTSS scores and CDSS scores, $r = .44$ ($n = 427$), $p < .001$, confirming the first hypothesis (path a in Figure 1). Children with greater exposure to disasters experienced higher levels of daily stressors.

The Relation Between War- and Tsunami-Related Stressors and Psychological and Psychosocial Functioning

Regression analyses using WTSS as the only predictor for each of the outcomes indicated that WTSS scores were significantly related to each outcome (see Model 1 in Table 3) except the S-Withdrawal subscale of the SLIPSS–C (path c in Figure 1). Exposure to war- and tsunami-related stressors was significantly related to increased PTSD ($\beta = .32$), Depression ($\beta = .23$), and Anxiety ($\beta = .33$), as well as to total SLIPSS–C ($\beta = .35$) scores and to two of its subscales, S-Internalizing ($\beta = .40$) and S-Externalizing ($\beta = .23$) scores ($p < .001$ for each of these outcomes). Because WTSS scores were not significantly related to S-Withdrawal scores ($\beta = .01$), no further regression analyses were conducted with this subscale. Thus, the second set of hypotheses was confirmed for all but S-Withdrawal. Exposure to stressors associated with war and tsunami significantly predicted poorer psychological and psychosocial functioning.

The Contribution of Daily Stressors Beyond WTSS in Predicting Psychological and Psychosocial Functioning

Regression analyses using both WTSS and CDSS as predictors indicated that CDSS scores contributed beyond WTSS to predict all six outcome measures (see Model 2 in Table 3; path b in Figure 1). Controlling for WTSS, the CDSS total score significantly predicted PTSD ($\beta = .40$), Depression ($\beta = .22$), and Anxiety ($\beta = .35$) scores, as well as the overall SLIPSS–C ($\beta = .25$) and the two subscales of S-Internalizing ($\beta = .27$) and S-Externalizing ($\beta = .19$) ($p < .001$ for all analyses) scores. Thus, the third set of hypotheses was confirmed: Exposure to daily stressors was significantly predictive of poorer psychological and psychosocial functioning, beyond that which can be predicted by exposure to the war and tsunami.

Daily Stressors as Mediators Between War- and Tsunami-Related Stressors and Outcomes

Total CDSS scale as a mediator. Model 1 in Table 3 provides the beta weights of the WTSS in regression analyses predicting each of the six outcome variables. These weights are represented by path c in Figure 1. Model 2 in Table 3 provides the regression weights when both WTSS and CDSS are used to predict each of the outcomes. The regression weights for WTSS and CDSS correspond to paths c′ and b, respectively, in Figure 1. The corre-

Note. All tests are two-tailed. Numbers in bold indicate $p < .001$. PTSD = posttraumatic stress disorder; SLIPSS–C = Sri Lankan Index of Psychosocial Status for Children; S-Internalizing = Internalizing subscale of the SLIPSS–C; S-Externalizing = Externalizing subscale of the SLIPSS–C; WTSS = War- and Tsunami-Related Stressor Scale; CDSS = Children's Daily Stressor Scale.
$^*p < .05$. $^{**}p < .01$.

lation between WTSS and CDSS is .44, represented by path a. The mediation effect can be observed as the reduction in the beta weight for WTSS when the mediator is added to the model. For predicting PTSD, we find this reduction to be substantial: c–c′ = .315–.137 = .178.

An equivalent way to compute the mediation effect is the product of the regression weights for the paths through the mediator, paths a and b. For predicting PTSD with CDSS as a mediator, this product is .444 × .401 = .178, the same value as c–c′. Both paths a and b are statistically significant with $p < .001$, which we take as evidence that daily stressors (CDSS) mediate at least partially the relation between exposure to the stressors of war and tsunami (WTSS) and PTSD. Statistical significance of the a × b index of mediation can also be tested with the Sobel test (Sobel, 1982), which yields $z = 5.33$, $p < .001$.

The beta weights for the CDSS (Model 2 in Table 3) are statistically significant ($p < .001$) for each of the six outcome variables. Thus, the CDSS mediates between WTSS scores and scores on PTSD, Depression, Anxiety, and SLIPSS–C (total, as well as S-Internalizing and S-Externalizing) scales. In each model, the mediation effect is partial rather than complete because although the beta weights on the WTSS are reduced for all outcome measures, they do not reduce to zero but rather remain statistically significant with $p < .001$ for PTSD, SLIPSS–C, S-Internalizing, and Anxiety scores.

The final rows of Table 3 provide the R^2 added when WTSS is entered at the first step of a hierarchical regression and when CDSS entered at the second step ($p < .001$ for all six outcome variables). Examination of these R^2 values demonstrates that the CDSS approximately doubles the variance explained by the WTSS alone in predicting PTSD, Depression, and Anxiety.

The individual subscales of the CDSS as mediators. Because CDSS scores were significantly and meaningfully related to the six outcome measures, and because three conceptually distinct factors emerged from factor analyzing the CDSS, separate mediation analyses were conducted using each of the three subscales of the CDSS (Deprivation, Interparental Conflict, and Abuse; Models 3, 4, and 5 in Table 3).

As a first step, the relations between WTSS scores and each of the three subscale scores (path a) were tested. The WTSS was correlated with two of the three subscale scores of CDSS: Deprivation ($r = .42$, $p < .001$) and Abuse ($r = .27$, $p < .001$). Because path a was not significant for Interparental Conflict ($r = .02$, $p > .05$), this factor cannot function as a mediator between WTSS and the outcome variables; no further mediation analyses were conducted with this variable.

As shown in Model 5 (Table 3), Abuse was a significant predictor of each measure of psychological and psychosocial functioning, beyond the contribution of WTSS. The beta values ranged from .20 for Depression to .33 for S-Externalizing ($p < .001$ for each of these path b beta weights). Thus, Abuse was a strong mediator of the relation between WTSS and each of the outcome measures. Deprivation also clearly mediated the relation between WTSS and three of the outcome measures: PTSD ($\beta = .29$), Anxiety ($\beta = .28$), and S-Internalizing ($\beta = .18$), all $p < .001$. Evidence for mediation was present but weaker for the total SLIPSS–C ($\beta = .11$, $p < .05$) and Depression ($\beta = .12$, $p < .05$) scores. These results confirm our fourth set of hypotheses, providing strong evidence for mediating effects of the daily stressors of deprivation and abuse on the relationship between exposure to war and the tsunami and distress in youth.

Multiple mediator models. The three subscales of the CDSS were moderately correlated. The correlation of Deprivation with Interparental Conflict was $r = .19$ and with Abuse was $r = .23$, whereas the correlation between Interparental Conflict and Abuse was $r = .19$ (all $ns = 427$, $ps < .001$).

Mediation effects and the unique contributions of each variable are shown in Model 6 (Table 3). The Abuse subscale of the CDSS demonstrated significant and unique mediating effects with all outcome measures ($p < .001$ for the relation with each outcome variable). The direct paths (c′) for the WTSS were significantly greater than zero ($p < .001$ for all outcome variables except Depression scores, where $p < .01$), indicating that the mediation effect was only partial. The unique mediation effects of Deprivation and Interparental Conflict scores were generally weaker, although the Deprivation subscale showed unique mediation effects in predicting PTSD, S-Internalizing, and Anxiety scores ($p < .001$).

When age, gender, and ethnicity were included along with the WTSS and the three CDSS subscales as predictors, age did not add unique variance to predicting any of the six psychological and psychosocial outcomes, whereas gender and ethnicity did explain variance in some models. Controlling for all other variables, being female predicted higher Anxiety ($\beta = -.16$) and S-Internalizing ($\beta = -.20$), whereas being male predicted higher S-Externalizing ($\beta = .17$). Compared to the Sinhalese youth, Muslim youth obtained significantly higher Anxiety ($\beta = .17$), total SLIPSS–C ($\beta = .24$), and S-Internalizing ($\beta = .23$) scores. Even with the demographic variables entered into the model, CDSS scores contributed beyond these variables and WTSS scores in predicting all six outcomes, with R^2 changes of .12 for PTSD and .10 for total SLIPSS–C scores. When demographic variables were included in the model, WTSS scores contributed uniquely toward predicting PTSD, SLIPSS–C, and S-Internalizing scores but not to predicting the other three outcome variables. Space limitations preclude more in-depth analyses of the relation of the demographic variables with the outcome measures but are available elsewhere (Fernando et al., 2008).

Summary of Analyses

Taken together, the results convincingly demonstrate that daily stressors mediate the relation between exposure to disaster-related stressors and psychological and psychosocial outcomes for Sri Lankan youth. As summarized in Table 3, the total CDSS score and the subscales of Deprivation and Abuse significantly mediated the relation between WTSS scores and most of the outcomes (PTSD, depression, anxiety, and two subdomains of psychosocial status). These findings held even when age, gender, and ethnicity were statistically controlled. The subscales of daily stressors demonstrated distinct predictive patterns (see Table 3, Model 6) with all predictors in the model: Deprivation was a strong predictor of PTSD and Anxiety but not of Psychosocial Status. In contrast, Abuse was a relatively stronger predictor of Psychosocial Status than of PTSD. In particular, S-Externalizing was strongly predicted by Abuse ($\beta = .32$) but not by Deprivation ($\beta = .07$). Figure 2 uses data from Table 3 (Models 1 and 6) to graphically represent how two of the three subscales of the CDSS mediate the relation between the WTSS and PTSD.

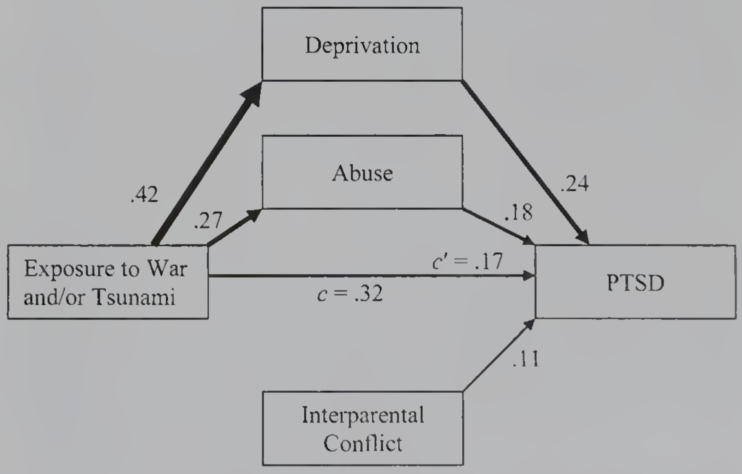

Figure 2. Daily stressors as mediators of the relation between exposure to war and/or tsunami and posttraumatic stress disorder ($n = 427$).

Discussion

In this study, we sought to examine the relative contribution of disaster exposure, on one hand, and daily stressors, on the other, to the mental health and psychosocial functioning of youth in a region of eastern Sri Lanka sorely affected by a prolonged civil war and a devastating tsunami. We also sought to assess the extent to which daily stressors mediate or explain the relation between disaster exposure and children's mental health. Using a multiethnic sample that reflected the ethnically diverse population of Sri Lanka in general and the Ampara district in particular, we used focus groups with youth to identify salient, proximal stressors in their social and material ecologies. Items were used to develop a self-report measure of daily stressors (the CDSS), which was subsequently used with self-report measures of war and tsunami exposure, PTSD, depression, anxiety, and a culturally specific measure of psychosocial distress.

The two issues we highlighted earlier in this study were addressed in this study. First was the tendency of researchers to focus solely on direct exposure to disasters as predictors of distress in children. As in much of the previous research with youth in settings of armed conflict and natural disaster, the results of this study demonstrated that exposure to disaster-related violence and loss was significantly related to the psychological and psychosocial distress of Sri Lankan youth. Limiting our analyses to these relations, a strong case could be made for trauma-focused interventions to be conducted with this group. However, and consistent with our hypotheses, the addition of daily stressors to the models markedly reduced the power of disaster exposure to predict the psychological and psychosocial distress of Sri Lankan youth, even that of PTSD (see Figure 2). The daily stressors taken together were stronger predictors of PTSD than direct exposure to the conflict and the tsunami, and about as strong a predictor of the other measures of psychological and psychosocial distress. Moreover, as hypothesized, daily stressors partially mediated the relation between direct exposure to conflict and tsunami and resulting distress of Sri Lankan youth. Thus, the failure to include daily stressors in explanatory models of distress among young people in emergency settings is likely to overestimate significantly the predictive power of disaster exposure, and to overlook critical sources of variance in youth well-being or distress.

When the CDSS subscales identified through factor analysis were entered into the mediation models, several key findings emerged, all consistent with our hypotheses and the models depicted in Figures 1 and 2. First, material deprivation, witnessing interparental conflict, and being the victim of child abuse all contributed significantly to psychological and psychosocial distress, although the strength of these relations varied depending on the outcome variable used in each model. Importantly, both child abuse and deprivation predicted PTSD as well as or better than direct exposure to the war and tsunami (see Table 3 and Figure 2); clearly, therefore, our findings suggest that *direct exposure to armed conflict and natural disaster was neither the only nor even the primary source of traumatic stress in these children's lives*. We also found, as hypothesized, that the effects of exposure to disaster on the functioning of these Sri Lankan youth were at least partially mediated by experiences of material deprivation and child abuse. This study found empirical evidence that conflict and natural disasters generate conditions of deprivation for children and their families (e.g., diminished access to basic resources). That such deprivation should in turn affect young people's well-being is not surprising.

On the other hand, the mediating role of child abuse is less readily interpreted. The findings, however, do support Somasundaram's (2003) claim that the war, in particular, may be creating a culture of violence, where overall incidents of individual and family violence increase. In addition to physical abuse, several items on the abuse subscale also reflect actual or feared experiences of sexual abuse, and were endorsed by youth of both sexes (with boys reporting more sexual and physical abuse than girls). It may be that the generally stressful social conditions created by disaster reduce the patience and increase the reactivity of parents and teachers, making physical abuse (especially against boys) more likely. It may also be that conditions of war weaken social norms that otherwise protect children from being physically and sexually victimized. Additionally, in the crowded confines of camps for displaced families, privacy and parental protection are diminished and the potential for sexual abuse is increased.

We did not assess the sources of actual or feared abuse; consequently, we do not know whether the youth in our sample were primarily concerned with physical and sexual abuse by teachers, older youth, relatives, armed combatants, or other adults such as police officers. Anecdotally, we have heard that older school boys sometimes prey upon younger boys to obtain sexual pleasure, as sexual contact between young men and women is restricted in Sri Lanka due to strict sociocultural and religious norms. Follow-up research, conducted in a culturally sensitive manner, could examine the sources and nature of sexual and physical abuse of both young men and women in Sri Lanka, and how conditions of war and natural disasters might exacerbate these traumatic, yet preventable events.

Finally, as hypothesized in Figure 1 and depicted as an example in Figure 2, a subset of daily stressors, interparental conflict, was unrelated to war and tsunami exposure but did exert a significant effect on PTSD, anxiety, psychosocial status in general, and externalizing psychosocial behavior in particular. Focusing solely on disaster-related variables would have failed to pick up these important relations between daily stressors and distress among Sri Lankan youth.

The second issue we addressed was the tendency of some trauma researchers to focus on PTSD and other psychiatric symptomatology as the main outcomes of interest when assessing distress in youth living in disaster settings. The results of this study indicate that although PTSD was a valid outcome to assess, the addition of the domain of psychosocial status provided a broader and more culturally relevant understanding of the relation between disaster exposure and distress in Sri Lankan youth. Gender and ethnic group differences were obtained for psychosocial status, particularly for internalizing behavior, where girls and Muslim youth reported significantly higher internalizing behavior compared to boys and to Sinhalese and Tamil youth, respectively. Tamil youth in turn reported significantly higher internalizing behavior compared to Sinhalese youth. No such group differences were obtained for PTSD scores. Given that Muslim youth also reported significantly higher exposure to the war and tsunami, as well as to daily stressors, it is interesting that the outcome of PTSD, which is sensitive to trauma exposure, did not show such group differences. Thus, in this study, the addition of a locally developed measure of psychosocial status provided a more comprehensive picture of how both disaster-related and daily stressors impact the psychosocial well-being of youth, compared with focusing solely on PTSD as an outcome. Additionally, although we did not focus on the outcome of anxiety as a measure of distress, the MASC (the measure of anxiety used for this study) was more sensitive to both disaster-related and daily stressors, compared with the measure of PTSD. This suggests that when working in Sri Lanka with scarce resources, it may be more useful to use the SLIPSS–C and MASC as outcome measures.

The Relation of Demographic Variables to Predictors and Outcomes

Examination of the relation between demographic variables (age, gender, and ethnic group membership) and exposure to disaster-related stressors and daily stressors revealed that although older age was related to greater exposure to daily stressors, age did not significantly predict any assessed outcomes. Gender was not significantly related to predictors but was significantly related to psychosocial outcomes; consistent with other studies (e.g., Montgomery, 2008), girls reported significantly higher internalizing tendencies and anxiety, whereas boys reported significantly higher externalizing behaviors.

Ethnic group membership was related to both predictors and outcomes. Exposure to disaster-related stressors was greater for the Tamil and Muslim youth than for Sinhalese youth. Additionally, Muslim and Tamil youth showed greater levels of deprivation than Sinhalese youth, and Muslim youth reported higher levels of abuse than Sinhalese youth. Conversely, Sinhalese youth reported significantly greater exposure to interparental conflict compared to Muslim youth. In terms of outcomes, the most striking difference was between Sinhalese and Muslim youth; the latter reported significantly higher depression, anxiety, and internalized psychosocial distress, compared to Sinhalese children. There is evidence that Sri Lankan Muslims are often ignored in the debate about where to allocate scarce economic resources (International Crisis Group, 2007); these results speak to an urgent need to ensure that intervention programs target this at-risk ethnic minority group. Additionally, more studies should be conducted to determine whether the findings obtained here about specific ethnic groups enduring different types of hardship are robust.

Implications of Results for Practice and Policy

There is a growing debate regarding the relative priority of trauma-focused versus more holistic psychosocial interventions with children in settings of armed conflict and natural disaster. On one side of this debate, proponents of trauma-focused models point to elevated rates of PTSD symptoms among children in emergency settings as evidence that intervention efforts should aim primarily at the amelioration of psychological trauma resulting from exposure to war and disaster using specialized trauma treatment programs (Neuner et al., 2006; Yule, 2002). Implicit in this view is a particular set of assumptions: (a) PTSD is valid and meaningful diagnostic construct for children regardless of the cultural context; (b) PTSD, rather than other expressions of distress, represents the most critical indicator of children's mental health in situations of war and disaster; and (c) children's distress in emergency settings is primarily related to traumatic exposure to war- and disaster-related violence and loss.

Advocates of more holistic psychosocial approaches challenge these assumptions and argue instead for community-based approaches that strengthen naturally occurring support systems, normalize children's daily routines, and provide child-friendly spaces in schools and other locales for activities that promote recovery without focusing specifically on trauma. These researchers maintain that the cross-cultural validity of PTSD has generally been assumed rather than systematically evaluated, and that even when symptoms of PTSD are present, they may be of secondary concern to families in cultural contexts where other expressions of distress may hold greater salience (de Berry et al., 2003; Hart et al., 2007; Kalksma-Van Lith, 2007; Miller & Fernando, 2008; Miller et al., 2009; Wessells & Monteiro, 2006). These researchers also argue that by focusing so narrowly on the posttraumatic effects of war- and disaster-related violence and loss, insufficient attention is paid to *ongoing* sources of stress in children's lives that may be amenable to change through targeted interventions (Barenbaum et al., 2004; Belfer, 2006). Finally, advocates of psychosocial approaches point to findings that symptoms of distress, including trauma, tend to abate in many children given adequate social support, the normalization of circumstances, and the passing of time (Belfer, 2006; Thabet & Vostanis, 2000; Wessells & Monteiro, 2006).

The results of this study shed additional empirical light on a debate that has, to date, been grounded largely in clinical and field experience as well as in competing ideologies. Our findings suggest some clear, if somewhat nuanced conclusions. First, although our data do not speak to the clinical utility or cultural salience of PTSD as a diagnostic construct in Sri Lanka, the syndrome was clearly present in our sample and was significantly related to disaster exposure as well as to daily stressors. Currently, we do not know whether PTSD represents the most meaningful expression of posttraumatic distress among Sri Lankan youth. However, PTSD was sensitive to the predictors of interest in this study. Second, although war and disaster did exert a direct effect on psychological and psychosocial health among the youth in our sample, material deprivation, physical and sexual abuse, and witnessing interparental conflict also represented major sources of ongoing stress. With specific regard to PTSD, daily stressors accounted for significantly greater variance in PTSD levels, indicating that there are critical sources of traumatic stress affecting youth in eastern Sri Lanka other than their history of exposure to the conflict and the tsunami.

Unlike prior exposure to the conflict or the tsunami, daily stressors represent *current* and proximal sources of stress in children's lives and may be targeted for change. Our data strongly suggest several potentially effective strategies for improving young people's psychosocial well-being in this and other regions of Sri Lanka, including the development or expansion of child abuse prevention programs and greater attention to meeting the basic material needs of children and youth. Having adequate access to water, safe housing, and schooling are all related to children's well-being. Focus group discussions with children in refugee camps adjacent to swamps indicated that one of the greatest sources of stress for these children was the presence of poisonous snakes, which restricted people from going for water after dark, and generated considerable fear when walking to the toilets at night. This sort of proximal threat loomed considerably larger for children than memories of the tsunami that had occurred several months earlier.

Limitations

There are several limitations in this study that suggest caution when interpreting the results. The first is the use of a composite score of war- and tsunami-related stress. It could be argued that war-related events lead to different types of psychological outcomes, compared to tsunami-related events, and that a composite score may not capture how exposure to a single disastrous event could result in specific distress for a child. Although a significant linear relation was obtained between the composite score and outcomes, future research could examine which particular types of events are associated with specific outcomes. In this study, we wished to point more to the general patterns of results. Another limitation is that by conducting the study in schools, we may have excluded children who were most affected by the war and the tsunami, such that they were unable to attend school. Teachers did indicate that all children attended school regularly, and attendance records demonstrated over 98% school attendance overall, but it is possible that the children absent on the day the survey was administered may have been systematically different from the children who completed the survey, biasing the data.

Caution should also be used in generalizing the findings to all Sri Lankan youth or to a specific ethnocultural group, as the data were gathered in a particular setting where both the tsunami and the war had occurred. Lower reliability on some subscales of the measures also suggests caution in overinterpreting results until more studies are conducted that establish the relations found here. However, lower Cronbach's alpha is likely to underestimate reliability for the event-based scales used in this study. Because exposure to various disaster experiences does not necessarily co-occur, Cronbach's measure of internal consistency may be less relevant for such scales. More importantly, as Netland (2005) argues, war (and by extension, natural disaster) exposure scales should include the full range of events to which people may be exposed in a particular region. Our study did include such a range. Future research could also use teacher and parent reports against which self-report data could be compared, providing a more appropriate index of reliability for such measures of exposure and overcoming the added limitation of reliance on self-report.

Because we relied on the ability of children to read and comprehend the survey, younger children were not included in this study. Future research could include a wider age range, using methods such as stories and pictures to obtain similar information from younger children. The lack of longitudinal data also limits findings. The current study does not speak to how the developmental trajectory of children who report more distress may change as a function of exposure to disaster-related stress, and interfere with developmental tasks of childhood and adolescence, creating ongoing stress for these youth.

Adding other ecological dimensions such as parent characteristics and other cultural variables may have provided a richer profile of these youth, although many of these dimensions were captured in the SLIPSS–C. Future research could also examine how socioeconomic conditions might function as both mediators and moderators of outcomes for youth living in emergency settings. In a study conducted with Sri Lankan businessmen, de Mel, McKenzie, and Woodruff (2008) found that time, rather than economic recovery, was a better predictor of psychological recovery after trauma. Whether this is true for Sri Lankan children as well remains to be examined. In relation to this issue, although our model suggests that exposure to disasters predicts exposure to daily stressors, it is possible that a third variable (such as poverty) might be related to both, as well as to outcomes. It is not uncommon to find that far more poor than wealthy people reside in places where disasters typically strike. Thus, poverty may, on the one hand, place a child at risk for being in an undesirable location and, on the other, exacerbate the ill effects of exposure to stressors. The current model is only one perspective on the relationship between stressors and distress.

Despite these limitations, this study provides empirical evidence for the importance of examining daily stressors as significant contributors to the psychological and psychosocial distress of youth living in complex emergency settings, using culturally grounded measures. Although Sri Lanka's armed conflict is now officially ended, it must not be forgotten that its impact continues to be felt by Sri Lankans, particularly those living in the north and the east (CIDA, 2009; United Press International, 2008). Children and families there are struggling simply to survive. The results obtained in this study argue for more holistic and ecologically sound intervention programs that target specific stressors among Sri Lankan youth, to effect change and ameliorate the distress of this very vulnerable population.

Exploring Posttraumatic Growth in Children Impacted by Hurricane Katrina: Correlates of the Phenomenon and Developmental Considerations

Ryan P. Kilmer and Virginia Gil-Rivas
University of North Carolina at Charlotte

This study explored posttraumatic growth (PTG), positive change resulting from struggling with trauma, among 7- to 10-year-olds impacted by Hurricane Katrina. Analyses focused on child self-system functioning and cognitive processes, and the caregiving context, in predicting PTG at 2 time points (Time 1 n = 66, Time 2 n = 51). Findings suggest that rumination, both negative, distressing thoughts and constructive, repetitive thinking, plays an important role in PTG. Hypotheses regarding future expectations and perceived competence were not fully supported, and, unexpectedly, coping competency beliefs, realistic control attributions, and perceived caregiver warmth did not contribute to PTG models. With 1 exception (positive reframing coping advice), caregiver-reported variables did not relate to PTG; no caregiver variable reached significance in final models. Relevant theory, developmental considerations, and future directions are discussed.

The child disaster literature has largely focused on symptomatology and problem behaviors, primarily posttraumatic stress symptoms (PTSS) and posttraumatic stress disorder (PTSD), and factors that appear to influence children's adjustment (Silverman & La Greca, 2002). While that work has yielded necessary findings about the consequences of disaster and informed subsequent research, intervention, and policy, this evolving field needs to go beyond negative sequelae and elucidate factors that may mitigate the impact of disaster, as well as factors and conditions that contribute to resilience and processes such as *posttraumatic growth* (PTG; Alisic, van der Schoot, van Ginkel, & Kleber, 2008; Kilmer & Gil-Rivas, 2010).

PTG refers to positive change experienced as a result of the struggle with trauma. Emphasizing the transformative elements of responding to adversity, PTG has been the focus of burgeoning interest in the research and clinical literatures (e.g., Calhoun & Tedeschi, 2006; Helgeson, Reynolds, & Tomich, 2006). However, despite this attention, and the significant research base regarding children and youth's response to stress or trauma (Compas, Connor-Smith, Saltzman, Harding Thomsen, & Wadsworth, 2001; Grant et al., 2003; Osofsky, 2004a), relatively few studies have examined the construct among children. Notably, the report of the Hurricane Katrina Community Advisory Group (HKCAG, 2006) assessed PTG; however, it did so only among adults.

Nevertheless, early evidence supports the conclusion that growth occurs in some form among children and youth who have experienced natural disasters (Cryder, Kilmer, Tedeschi, & Calhoun, 2006; Kilmer et al., 2009), terrorism (e.g., Laufer & Solomon, 2006), traffic accidents (Salter & Stallard, 2004), cancer (e.g., Barakat, Alderfer, & Kazak, 2006), and a range of traumatic events (e.g., Alisic et al., 2008; Ickovics et al., 2006; Milam, Ritt-Olson, & Unger, 2004). However, the literature appears to include only four published papers (Alisic et al., 2008; Cryder et al., 2006; Phipps, Long, & Ogden, 2007; Salter & Stallard, 2004) investigating PTG or related constructs (stress-related growth, perceived benefits, benefit finding) within a child sample or subsample. Of those, only Cryder et al. (2006) reported correlates of PTG reflecting resources, competencies, or processes thought to relate to the growth process. This article seeks to extend those findings and enhance understanding of PTG in children. It has the following objectives: (a) provide relevant conceptual background, considering developmental issues, distinguishing the construct from resilience, and discussing selected variables thought to be relevant to the PTG process and (b) examine

correlates of PTG. Specifically, informed by Kilmer's (2006) model of the growth process and ideas posited by Kilmer and Gil-Rivas (2010), the present work focuses on the role of child characteristics, including self-system variables (e.g., perceived competence, future expectations) and cognitive resources and processes (e.g., realistic control expectations, rumination), and indicators of the caregiving context (e.g., caregiver warmth, caregiver positive reframing coping advice) thought, on theoretical and/or empirical grounds, to be related to PTG.

PTG and the Growth Process

Although many children adapt successfully in the face of adversity, research has demonstrated that children who have experienced trauma may exhibit difficulties in multiple developmental domains, such as emotional and behavioral symptoms, delays or regressions in developmental skills, and difficulties in cognitive and socioemotional functioning (e.g., Cicchetti & Lynch, 1993). Disaster-specific work has reinforced such notions, suggesting that a sizable proportion of children evidence a range of short- and long-term mental health sequelae following disaster (e.g., La Greca, Silverman, Vernberg, & Roberts, 2002; Pfefferbaum et al., 1999), which vary based on a child's developmental level (see National Child Traumatic Stress Network [NCTSN], n.d.; Osofsky, Osofsky, & Harris, 2007). The most common long-term negative consequences reflect PTSD symptoms, anxiety and generalized distress, major depression, suicidality, and problem behaviors (e.g., Silverman & La Greca, 2002).

The child trauma literature has also described findings akin to PTG. For instance, work with pediatric cancer survivors suggested that youth experienced positive changes including heightened sensitivity to others, increased altruism, and modified values (Fritz, Williams, & Amylon, 1988). A recent study with youth aged 7–18 years who had experienced traffic accidents found that many reported a changed philosophy of life, improved relationships, and more positive self-perceptions after the accidents (Salter & Stallard, 2004). Others have documented instances of children reporting that they feel ''stronger'' after significant life events, such as the death of a parent (Krementz, 1983), and more systematic efforts, focusing on PTG, have found evidence supporting the phenomenon in children (Alisic et al., 2008; Cryder et al., 2006; Kilmer et al., 2009). In general, the literature suggests that the positive changes framed as PTG tend to cohere in several main domains: a greater sense of one's personal strength; a different perspective on one's relationships; a changed philosophy of life, such as a greater appreciation for life and its new possibilities; and spiritual growth (Calhoun & Tedeschi, 2006; Kilmer, 2006).

Key elements of the hypothesized PTG process warrant mention (see Kilmer, 2006). In many cases, traumas such as disaster can impact meaningfully a youngster's assumptive world. They can shatter assumptions about one's self, others, one's world, and the expected course of one's life (Janoff-Bulman, 1992), stimulating attempts to cope and adapt. Growth is thought to evolve as a result of the struggle with trauma and its aftermath, not solely the experience of the trauma itself, developing as one grapples with his or her new reality, working to understand what has happened and its implications for life going forward (Calhoun & Tedeschi, 2006). In fact, theorists postulate that this continuing distress and the individual's efforts to reconcile his or her posttrauma reality facilitate a constructive cognitive processing of trauma, or productive rumination (Calhoun & Tedeschi, 2006). Through this process, one may try to make sense of the event(s) and integrate the trauma and its aftermath in a manner consistent with prior internal representations, or working models. Subsequently, this ruminative process yields schema change, a critical element that serves to consolidate changed perspectives on self, others, and one's new life and way of living (Calhoun & Tedeschi, 2006). Of relevance here, existing evidence suggests that, following trauma, the reactions and responses of children and youth at different ages and stages vary, in part because their cognitive and emotional capacities lead them to understand and internalize the experience differently (NCTSN, n.d.; Osofsky, 2004b). In light of these realities, and because PTG appears to involve a degree of cognitive sophistication that allows both losses and gains to be recognized, the degree to which the growth process in children accords with the process observed among adults is unclear (Cryder et al., 2006).

Developmental Considerations in the Study of PTG

Questions have been raised about children's capacity to engage in the cognitive and affective processes necessary to yield transformational changes, including their ''psychological mindedness'' (intrapersonal awareness and insight) or self-understanding (Cryder et al., 2006; Kilmer, 2006). Variability in youngsters' cognitive capabilities may influence their encoding and appraisal of, and attributions about, trauma (Hasan & Power, 2004; Shahinfar & Fox, 1997), repertoire of coping strategies, ability to marshal resources and cope effectively, and capacity to attend to and report their internal experiences and emotional states (Alisic et al., 2008; Cryder et al., 2006; Kilmer, 2006; Osofsky, 2004b). Moreover, children's responses and reactions are closely tied to their cognitive, emotional, and behavioral capacities at the time of the trauma and the time of the expression of their responses posttrauma (Shahinfar & Fox, 1997). Although this study does not address these issues directly, several developmental considerations warrant a brief discussion, particularly the degree to which child self-reported PTG reflects actual growth versus normative maturation, and cognitive maturity and the appraisal and understanding of the event, including issues of self-awareness and self-understanding.

Some researchers have underscored the need to differentiate child PTG from change resulting from normal maturational processes (Cohen, Hettler, & Pane, 1998). Two recent efforts shed light on this valid issue. Taku, Calhoun, Kilmer, and Tedeschi (2008) found that, among Japanese youth (mean age = 13.52 years, *SD* = 0.97), those who reported experiencing at least one trauma or major stressful event within the past year scored significantly higher on a measure of PTG (and on 8 of its 10 items) than peers who had not (who, in response to the PTG measure's items, reported about the degree to which they had changed in the last year). In their community sample (mean age = 10.24 years, *SD* = 1.21), Alisic et al. (2008) asked children to describe their "worst experience ever" and to consider that experience as they answered items about PTSS and PTG. An expert panel then determined whether the events reported were consistent with the *DSM–IV* PTSD A1 criterion for objective trauma exposure (i.e., "the person experienced, witnessed, or was confronted with an event or events that involve actual or threatened death or serious injury; or threat to the physical integrity of himself or herself or others"; American Psychiatric Association [APA], 1994, p. 427) and classified children on the basis of their experiences (i.e., exposed or not exposed to trauma). Consistent with Taku et al., children exposed to trauma reported more PTG than those without trauma experiences (Alisic et al., 2008). While prospective-longitudinal methodologies are necessary to yield compelling evidence that the growth assessed is indeed PTG, these findings provide support for the PTG process as distinct from normal growth.

When considering cognitive maturity, some may question whether young children are sufficiently self-aware to reflect and consider the degree to which they have changed over time. Kilmer et al. (2009) reported responses to findings from open-ended items illustrating that, while few 7- to 10-year-olds spontaneously made comments that clearly suggested growth (e.g., "I am more positive now"), they demonstrated a grasp of the temporal element of the questions about change (e.g., "After the hurricanes, my grandfather died and my mother got meaner"). This capacity to make the temporal comparison is consistent with prior findings (Harter, 2006).

Beyond the temporal element, with cognitive maturity comes the capacity for greater self-understanding and awareness and more developed schema for oneself and one's world, key factors in the processes presumed relevant to growth. Findings regarding the impact of age have been mixed: Milam et al. (2004) found a positive association between age and PTG among adolescents, positing that a particular level of cognitive maturity is necessary to find meaning or identify salient positive changes as a result of trauma; however, in much younger samples, Cryder et al. (2006) and Kilmer et al. (2009) did not detect a relation between age and PTG.

Nevertheless, multiple salient capacities emerge in middle and late childhood that warrant mention, given their potential relevance to PTG. For example, during this time, children evidence increased competence in managing trauma-related thoughts and regulating their emotions (e.g., Salmon & Bryant, 2002). Thus, authors have noted an increase in emotion-focused coping and the manifestation of cognitively oriented attempts at coping, including cognitive reframing, or reappraising a difficult situation (e.g., Aldwin, 2007; Compas et al., 2001; Salmon & Bryant, 2002). Moreover, although findings vary regarding the ages at which this capacity coalesces, between ages 6 and 9, control expectations become more realistic, and children are better able to identify the ways in which they can cope with those circumstances that can and cannot be controlled (e.g., Aldwin, 2007; Salmon & Bryant, 2002).

Furthermore, given that (a) schema change and (b) the capacity to acknowledge and integrate the positives in oneself and one's situation following trauma constitute two critical elements of the hypothesized PTG process, it is necessary to highlight that young children's internal representations of self and others are not yet set and may be qualitatively different than those of adults. According to

Janoff-Bulman (1992), because a child's assumptive world is more pliable than an adult's, his or her basic assumptions and working models may be modified as new experiences become incorporated. Thus, exposure to trauma can severely disrupt one's assumptive world (e.g., of safety, predictability), because these cumulatively constructed representations are less firmly entrenched (Janoff-Bulman, 1992; Lieberman & Van Horn, 2004). However, that also suggests that the child's schema may be open to adaptive inputs (Janoff-Bulman, 1992), including the reworking and revision of one's views of oneself and one's world.

For that to occur, the child must recognize and internalize some positive appraisals of the trauma and subsequent changes. A line of research regarding children's ability to acknowledge the simultaneous existence of positive and negative emotions or attributes in relation to a target event (Harter, 1986; Harter & Buddin, 1987) may shed light on their capacities to accommodate a positive aspect or change in the face of trauma. Specifically, while 5- to 7-year-olds are generally unable to integrate emotions of opposing valence (both positive and negative), a developmental progression is evident such that children develop the capacity to understand and express emotions of different valence to a target between 9 and 13 years of age ($M = 11.34$, $SD = 2.12$), with some children evidencing this ability as young as 7.6 years (Harter, 1986; Harter & Buddin, 1987). These findings may suggest a lower age limit for PTG (Kilmer, 2006).

The PTG and Resilience Constructs: Parallel but Distinct

PTG clearly shares significant conceptual variance with the construct of resilience; however, they are distinct. While resilience refers to "a dynamic developmental process reflecting evidence of positive adaptation despite significant life adversity" (Cicchetti, 2003, p. xx; see Masten, 2001), PTG refers to a process by which one is *transformed* as a result of his or her struggle in trauma's aftermath (Cryder et al., 2006). Thus, PTG involves positive changes extending beyond sound adjustment despite adversity; it "involves movement beyond pretrauma adaptation, a qualitative change in functioning across domains" (Cryder et al., 2006, pp. 65–66).

That PTG does not equate to positive adjustment further distinguishes PTG and resilience. That is, those reporting PTG may also report less emotional well-being or positive adjustment than those evidencing resilient adaptation (Cryder et al., 2006). Although a recent prospective-longitudinal study with adolescents demonstrated that those who reported higher PTG exhibited less emotional distress up to 12 and 18 months postevent (Ickovics et al., 2006), and others have reported a link between PTG and health-related behaviors (Milam et al., 2004), the extant literature largely suggests that while many survivors recognize positive change as a result of their struggle, they often report distress and symptomatology in the aftermath of trauma (Calhoun & Tedeschi, 2006). Thus, growth and distress may coexist (Kilmer & Gil-Rivas, 2008). In that vein, Linley and Joseph (2004) suggested framing growth and distress as independent dimensions, not two ends of a single continuum. Accordingly, Salter and Stallard (2004) reported that while 42% of their sample reported PTG, 37% of these same children met criteria for a PTSD diagnosis. Similarly, Alisic et al. (2008) and Kilmer et al. (2009) found a significant positive correlation ($rs = .41$ and $.44$, respectively) between PTG and PTSS. Such findings are not inconsistent with PTG models—distress is viewed as a key catalytic element of the process and may serve to maintain growth (Tedeschi, Calhoun, & Cann, 2007).

Notwithstanding the differences between the constructs, the resilience research base can point to factors, processes, and conditions that may not only influence children's adjustment in response to trauma, including disaster, but may also hold promise in the study of PTG. For instance, most disaster studies have focused on relatively circumscribed individual characteristics (e.g., demographics) and elements of functioning, such as coping approaches (e.g., La Greca, Silverman, Vernberg, & Prinstein, 1996) or predisaster functioning (e.g., anxiety symptoms; see, e.g., Weems et al., 2007). Although these studies have yielded important findings, work in resilience suggests a far wider range of child variables that warrants investigation, particularly child attributes, resources, and competencies such as positive dispositional qualities, good intellectual functioning, self-efficacy, perceived competence, control attributions, and positive future expectations or optimism (e.g., Luthar, 2003; Masten & Coatsworth, 1998). Results from this work may inform PTG research.

Constructs of Relevance to the Present Study

Drawing from prior PTG research and theory (e.g., Cryder et al., 2006; Kilmer, 2006), as well as work in stress and coping and risk and resilience (e.g., Luthar, 2003; Masten & Coatsworth, 1998), the following constructs are of prime relevance to the present study.

Self-System Factors: Perceptions Regarding Competence and the Future

One's perceptions of competence, one's expectations for his or her future, and one's positive appraisals and expectations regarding one's ability to meet daily task demands, cope, and adjust in the face of stress or trauma are hypothesized to play a core role in the PTG process (Kilmer, 2006). Cryder et al. (2006) found a direct relation between competency beliefs and PTG and, in the resilience literature, positive self-views and self-system functioning are among the most consistently reported factors that seemingly serve a protective function, facilitating positive adaptation and reducing risk of maladjustment in the face of adversity (e.g., Luthar, Cicchetti, & Becker, 2000; Masten, 2001). For instance, perceived competence scores were among the most powerful discriminators of those demonstrating resilient versus maladjusted outcomes in two independent cohorts of children exposed to multiple risks (Cowen et al., 1992; Hoyt-Meyers et al., 1995). Additionally, in their influential work, Werner and Smith (1982) emphasized that those exhibiting resilient adaptation ''worked well, played well, loved well, and *expected* well'' (p. 153, italics added). Positive beliefs about one's competencies or future may influence how a youngster perceives an event, his or her responses to adversity, and the effort he or she sustains in wrestling with the event and its aftermath (e.g., Wyman, Cowen, Work, & Kerley, 1993). In turn, factors reflecting sound self-system functioning (e.g., future expectations, perceived competence) are hypothesized to relate directly to PTG because they may affect not only one's perceptions of these events and ability to deal with them but also one's approach to and persistence in coping and the likelihood of perceiving positive change (Kilmer, 2006).

Cognitive Resources: Realistic Control Expectations

Current PTG models highlight cognitive processes, including not only appraisals of the traumatic event but also control attributions and rumination (Calhoun & Tedeschi, 2006; Kilmer, 2006). The accuracy of children's control expectations can influence how they respond and react following adversity (see Wannon, 1990). Wyman (2003) argued that under adversity, realistic control—that is, accurate, age-appropriate perceptions about events, outcomes, and problems that are controllable and uncontrollable—may be more meaningful and adaptive for children than an undifferentiated internal locus of control, a hypothesis with some support (Cowen et al., 1992; Hoyt-Meyers et al., 1995). For example, children's realistic control expectations and attributions about their circumstances would seem salient in the postdisaster context, as they may influence their responses to adversity, coping approaches, affect regulation, and behavioral organization and goals (Kilmer, 2006; see Hasan & Power, 2004; Pynoos, Steinberg, & Wraith, 1995). In turn, Kilmer (2006) hypothesized that realistic control relates bidirectionally with other cognitive elements of the growth process, such as productive rumination, and with aspects of the self-system, including coping competency beliefs and hope for the future.

Productive Rumination

The function of rumination, or repetitive thought, is thought to be of particular import in the PTG process. Ruminative thinking can have negative consequences (intrusive rumination has been linked with depressive symptoms and anxiety) or can serve a more constructive function, for example, helping one to recover and perhaps even grow posttrauma (see Watkins, 2008). According to PTG models, disruptions to one's assumptive world and distress associated with trauma (including intrusive thinking) may result in productive, or deliberate, ruminative processes that are thought to help one better understand, engage, and perhaps find meaning in the event, allowing for the inclusion of positive appraisals. These positive appraisals facilitate schema change as one notes and integrates the changes in oneself and one's environment (Kilmer, 2006; Tedeschi et al., 2007). Kilmer (2006) hypothesized a link between deliberate ruminative thinking and self-system variables, and consistent with this notion, Cryder et al. (2006) reported a significant relation between rumination and children's competency beliefs, with the latter the prime proximal predictor of PTG. While the nature of the rumination–PTG relation is not clear, early indications suggest the amount of rumination alone is not a significant predictor of PTG (Cryder et al., 2006). It is possible the content of the repeated thoughts and the manner in which the individual engages them more actively contribute to, and perhaps catalyze, the growth process (Kilmer, 2006; Tedeschi et al., 2007).

The Caregiving Context

Caregivers and, more broadly, the caregiving context are widely recognized to play a central role in helping children adapt in the face of adversity (Luthar, 2003; Masten & Coatsworth, 1998) and, more specifically, disasters (Gil-Rivas, Holman, & Silver, 2004). Among many potentially salient elements of this context, caregiver functioning postdisaster (including distress and symptoms) may relate to their responsiveness and availability (affecting caregiver behaviors and support) as well as children's appraisals, interpretations, reactions, and behavior (Masten, Best, & Garmezy, 1990; Salmon & Bryant, 2002).

Caregivers can also help youngsters appraise and understand events and their emotions, provide support, share perspective, and guide or model coping (Gil-Rivas, Silver, Holman, McIntosh, & Poulin, 2007; Kliewer, Sandler, & Wolchik, 1994; Pynoos et al., 1995). In turn, coping advice involving positive reframing, that is, encouraging children to consider the positive, would seem germane to child PTG. In the same vein, caregiver PTG may evidence a meaningful link to child PTG, in part because their experiences may inform the manner by which they help the child craft narratives about, or increase understanding of, the changes that have occurred, and offer perspectives that can foster adaptive schema change (Calhoun & Tedeschi, 2006; Janoff-Bulman, 1992; Kilmer, 2006).

Researchers have emphasized that warm, nurturant caregiving can mitigate the impact of risk (Luthar et al., 2000; Masten & Coatsworth, 1998), and competent, developmentally appropriate parenting in the disaster's aftermath will facilitate attunement and responsiveness to children's needs (Kilmer, 2006). In addition, supportive and nurturant caregiver–child relationships are thought to positively influence children's self-views and self-system functioning (Yates, Egeland, & Sroufe, 2003). In the PTG literature, this possibility was borne out by the significant link identified between perceived support and children's coping competency beliefs (Cryder et al., 2006). Thus, within the PTG process, warm, responsive caregiving may contribute to PTG largely through its association with the self-system.

The Context of the Present Study: Children and Families Impacted by Hurricane Katrina

The adversities experienced and the consequences evidenced by the children and families impacted by Katrina have been well documented (Gil-Rivas, Kilmer, Hypes, & Roof, 2010; HKCAG, 2006; Osofsky, Osofsky, Kronenberg, & Cross, 2010; Weems et al., 2007). In describing the experiences of the sample studied in the present investigation, Gil-Rivas et al. (2010) noted that 86.8% endorsed experiencing at least one hurricane-related traumatic event, and 63.2% of children reported that Hurricane Katrina was one of the ''most scary'' events they had experienced. Overall, children reported experiencing considerable adversity and, in the face of such circumstances, 1-year post-Hurricane Katrina, 21% of the children obtained PTSS scores suggesting the presence of a probable PTSD diagnosis, and nearly all reported experiencing at least one PTSS much or most of the time during the previous month (Gil-Rivas et al., 2010).

Kilmer et al. (2009) examined PTG among those same children, validating the PTG measure and reporting that, at baseline (approximately 12 months postdisaster), roughly 50% of the sample obtained total scores, suggesting an average response of at least ''some'' perceived change, or growth, across the scale's items; 7.5% had scores suggesting average responses of ''a little'' change or less. Total PTG scores did not differ for boys and girls, and age did not correlate with PTG. Analyses examined the linkages between PTG and multiple trauma-related variables. Consistent with expectations, children's baseline PTG scores were not significantly associated with objective hurricane exposure, but children's self-reported subjective response to the event and self-reported PTSS correlated significantly with PTG. Regression analysis demonstrated that subjective response related to PTG over and above objective hurricane exposure, though, in the final model, only PTSS significantly explained variance in PTG scores. Similar findings held at follow-up, roughly 22 months posthurricane. For instance, 53% of the sample obtained PTG scores suggesting ''some'' perceived change or more; 13.2% had scores suggesting ''a little'' or less. Consistent with baseline results, there were no gender differences in PTG scores, and age did not relate to PTG. Although baseline PTSS correlated with PTG at follow-up, baseline PTG was the only significant predictor of PTG. Overall, these findings lay groundwork for the present study.

The Present Study

This study sought to extend previous PTG work (i.e., Cryder et al., 2006; Kilmer et al., 2009), enhance understanding of PTG, and expand its nomological network by exploring relations beyond those between PTG and trauma-related variables (e.g., subjective response, PTSS). Specifically, it examined associations between PTG, children's self-system and cognitive resources and processes, and the caregiving context in a sample of young children (aged 7–10 years) impacted by Hurricane Katrina. This age group was targeted because it would permit examination of relevant developmental considerations and change over time, particularly among key constructs hypothesized to be associated with PTG. Informed by prior research and theory (Cryder et al., 2006; Kilmer, 2006; Kilmer & Gil-Rivas, 2010), the age of the children (and their still-evolving self-systems), the presumed importance of the caregiving context, and the assumed role of ruminative thinking in catalyzing the PTG process, we expected that:

1. At baseline, self-system variables (perceived competence, future expectations, and coping competency beliefs) would relate positively to PTG.
2. At baseline, perceived caregiver warmth would relate to both self-system variables and PTG, caregiver distress would be negatively associated with PTG, and caregiver PTG and positive reframing coping advice would be positively associated with child PTG.
3. At baseline, cognitive variables, particularly deliberate rumination, would evidence a positive association with PTG, over and above caregiver and self-system variables.
4. Baseline levels of child self-system functioning, rumination (intrusive and deliberate), and caregiver's positive reframing coping advice would predict PTG at follow-up, over and above PTG at baseline.

Method

Participant Recruitment and Study Design

Face-to-face interviews were conducted with children and their primary caregiver in the Baton Rouge and New Orleans, Louisiana metropolitan areas and along the Mississippi Gulf Coast. Baseline interviews were conducted roughly 1 year post-Hurricane Katrina ($M = 12.62$ months, $SD = 4.08$); follow-up interviews were conducted approximately 2 years posthurricane ($M = 22.36$ months, $SD = 3.25$). Participants were recruited via flyers distributed at elementary schools, Federal Emergency Management Agency (FEMA)-operated trailer parks, service provider agencies, and community-based organizations, and via participant referral. Trained research assistants conducted the interviews at participants' homes or at locations convenient to caregivers. Participants were compensated with gift cards for their participation and that of their child. The study was approved by the University of North Carolina at Charlotte and the Louisiana State University Institutional Review Boards.

Participants

At baseline (T1), participants included 66 caregiver–child dyads; of these, 51 completed the follow-up (T2) interview (77% retention). At T1, children, on average, were 8.5 years of age ($SD = 1.1$), and 56.1% were female. A majority of children were African American (77.3%), 15.2% were White, and 7.5% reflected other backgrounds. Caregivers were predominantly female (87.9%), and on average, they were 38.1 years old ($SD = 9.6$); 80.9% of them were the biological parent. Over half (63.6%) of the caregivers had a general equivalency diploma (GED) or high school diploma or less. Just over one third (34.9%) of the caregivers were married or living as married, 31.8% were divorced or separated, and 33.3% were single. Roughly two thirds (68.2%) of caregivers were unemployed, and 56.1% reported an annual household income of < \$9,999; an additional 16.7% had an income of < \$20,000. Nearly all children (97.0%) were directly exposed to the hurricane (i.e., they were in a building that was damaged, were injured, or were in a community that was flooded; a family member was injured or killed; or they otherwise experienced a loss) and, as a result, 95.7% of the families had to evacuate their communities and 90.0% became homeless. In the year following the hurricane, families moved an average of 3.1 times ($SD = 2.1$, range = 0–11). At T1, 36.4% of participants were living in FEMA trailers, 16.7% in their own house or apartment, 37.9% in a rented apartment or house, 6.1% lived with relatives, and 2.9% reported other living arrangements.

Measures

Children completed the following measures at T1, unless otherwise noted.

Hurricane-related exposure. Children completed an eight-item checklist that parallels in content the Hurricane-Related Exposure scale (La Greca et al., 1996; e.g., "You were injured or hurt"). A total score of events reported was computed.

Child PTSS. The UCLA PTSD Reaction Index (UCLA PTSD–R1; Steinberg, Brymer, Decker, & Pynoos, 2004) assessed PTSS at T1 and T2. The scale reflects *DSM–IV* (APA, 1994) PTSD-related symptoms: reexperiencing (i.e., intrusive memories, nightmares; five items), arousal (i.e., irritability, sleep difficulties; five items), and avoidance (i.e., avoiding people, activities, feelings; seven items). The scale also includes two items assessing other symptoms of clinical significance (i.e., fears of recurrence and trauma-related guilt). Children reported how much of the time they had experienced these symptoms in relation to Hurricane Katrina during the past month on a scale ranging from 0 (*none*) to 4 (*most of the time*). The UCLA PTSD–R1 has demonstrated good internal consistency and test–retest reliability. A PTSS total score was computed, using the method specified by Steinberg et al. (2004); α in this sample = .88.

Posttraumatic growth. The Posttraumatic Growth Inventory for Children–Revised (PTGI-C–R; Kilmer et al., 2009) was administered at T1 and T2. Each youth responded to open-ended items assessing changes perceived in their lives and themselves since Katrina. Children also responded to 10 items assessing changes in five PTG domains: *New Possibilities* ("I have new ideas about how I want things to be when I grow up"), *Relating to Others* ("I feel closer to other people [friends and family] than I used to"), *Personal Strength* ("I learned that I can deal with more things than I thought"), *Appreciation of Life* ("I know what is important to me better than I used to"), and *Spiritual Change* ("My faith [belief] in God is stronger than it was before"; Kilmer et al., 2009). Children responded on a 4-point scale (0 = *no change*, 1 = *a little change*, 2 = *some change*, 3 = *a lot of change*). Consistent with prior work, a total score was computed by summing the items; the scale demonstrated adequate internal reliability at T1 (α = .77) and T2 (α = .81).

Coping competency beliefs. This adaptation of the five-item Children's Competency Beliefs Scale (CCBS; Weyer & Sandler, 1998) used in a study of children displaced by Hurricane Floyd (Cryder et al., 2006) assessed children's perceptions of their ability to handle problems related to the hurricane (e.g., "Overall, I think that the things I did after the hurricanes worked to make things go better for me"), as well as other areas of their life (e.g., "I feel good about the way I have tried to handle my problems"), using a 0 (*not at all true for me*) to 3 (*very true for me*) scale. Mean scores were created; higher scores indicate greater coping competence (α = .63).

Perceived competence. Adapted from Harter's (1982) Self Perception Profile for Children, this 28-item version employs simplified item wording and a single-step forced-choice format (instead of the original's two-stage forced-choice response) to assess self-views of *Social Competence/Acceptance*, *Scholastic Competence*, *Behavioral Conduct*, *Athletic Competence*, *Physical Appearance*, and *Global Self-Worth* (Hoyt-Meyers et al., 1995). For each item, youth indicated which of two statements better described them (e.g., "I don't have as many friends as I'd like" vs. "I have lots of friends"). Items indicating greater perceived competency were coded as 1 and those reflecting lower competence as 0; responses were summed (α = .83).

Future expectations. This seven-item adaptation of Wyman et al.'s (1993) scale assesses youngster's views about their futures (e.g., the degree to which they expect to have a happy life, have friends and people who care about them) on a 3-point scale. The scale was modified to add structure and simplify responses for young children (Kilmer, 1996). Items were summed to create a total score; higher scores suggest more positive future expectations (α = .73).

Realistic control expectations. This adaptation of Wannon's (1990) measure assessed control expectations for controllable (e.g., "can children keep from failing a test if they study?") and uncontrollable (e.g., "can children keep adults from having any worries?") events, using a 3-point scale. This modification retained 11 of 12 items from the scale used by Hoyt-Meyers et al. (1995), dropping one of the two items excluded by Kilmer (1996) to reduce redundancy. Controllable and uncontrollable subscale αs = .70 and .52, respectively; given the low alpha, the latter was not included in analyses. Higher mean scores indicate more accurate expectations.

Rumination Scale for children. Used by Cryder et al. (2006), this five-item adaptation of the adult Rumination Scale (Calhoun, Cann, Tedeschi, & McMillan, 2000) measures intrusive (two items; e.g., "I think about it when I don't mean to") and deliberate rumination, (three items; e.g., "Sometimes I think about it to try to figure out why things like that happen"). Children responded using a scale from 1 (*not at all true for me*) to 4 (*very true for me*); a mean score for each subscale was created to facilitate interpretation. The correlation between the items reflecting intrusive thoughts was .33; the deliberate rumination subscale α = .65.

Caregiver warmth and acceptance. Children completed a 10-item version of a scale used previously to assess perceptions of caregiver warmth and acceptance (e.g., "My caregiver really understands me'' and ''My caregiver enjoys spending time with me''; Greenberger & Chen, 1996). Respondents used a 1 (*not all true*) to 4 (*very true*) scale, and a mean score was created (α = .68).

Caregivers completed the following measures at T1.

Demographic characteristics. Caregivers provided information regarding their age, gender, ethnic background, marital status, employment, annual income, and housing status. In addition, caregivers provided information regarding their child's age, grade, and ethnicity.

Psychological distress. The Hopkins Symptom Checklist–25 (HSCL–25; Derogatis, Lipman, Rickels, Uhlenluth, & Covi, 1974) assessed symptoms of depression, anxiety, and somatization. Caregivers indicated how frequently they had experienced symptoms over the past week using a scale from 0 (*not at all*) to 3 (*extremely*). A mean score was computed (α = .96).

Posttraumatic growth. Caregivers completed the 21-item PTGI (Tedeschi & Calhoun, 1996) at T1. Caregivers indicated to what extent they had experienced changes in their lives and themselves as a result of Katrina and its aftermath on a scale ranging from 0 (*no change*) to 5 (*a great deal of change*); a total summary score was computed. The scale demonstrated excellent internal reliability (α = .94).

Positive reframing coping advice. At T1 caregivers answered two items assessing how frequently they had encouraged their child to use positive reframing to cope postdisaster (e.g., ''encouraged [my child] to see the positive in what happened''; Gil-Rivas et al., 2007). They responded on a 0 (*not at all*) to 4 (*most of the time*) scale. A mean score was created; item r = .34.

Plan of Analysis

Correlations examined associations between key variables. Hierarchical multiple regressions explored correlates of children's PTG scores at T1 by entering caregiver variables in Step 1, child self-system variables and realistic control expectations in Step 2, and intrusive and deliberate rumination in Step 3. At T2, structurally similar regression analyses tested correlates of PTG after controlling for T1 PTG. In an effort to identify the most parsimonious model, variables not associated with PTG at $p < .10$ (on the basis of bivariate correlations) were excluded from the final analyses. As distress has been hypothesized to serve a catalytic role in the PTG process, and PTSS have been shown to be significantly associated with PTG (e.g., Alisic et al., 2008; Kilmer et al., 2009; Salter & Stallard, 2004), similar analyses included concurrent child-reported PTSS to determine the extent to which these symptoms influenced the pattern of relations identified. Finally, as children's perceived coping competency, control expectations, and rumination may vary by age, the following interaction terms were tested: Age × Coping Competency Beliefs, Age × Control Expectations, Age × Intrusive Rumination, and Age × Deliberate Rumination.

Attrition analyses were conducted to determine whether children who did not participate at T2 (n = 15) were significantly different from those who completed the follow-up (n = 51). No significant differences were identified in demographics and the study's core variables.

Results

Table 1 presents descriptive statistics for key study variables. Overall, children reported moderate levels of PTG and mild to moderate levels of PTSS at T1 and T2. Children reported positive future expectations and moderate levels of perceived competence, realistic control expectations, perceived coping competence, and intrusive and deliberate event-related rumination. Overall, children perceived their primary caregiver as warm and

accepting. Caregivers reported mild levels of distress, moderate levels of PTG, and having provided their child with positive reframing coping advice a good portion of the time.

Associations Among Key Variables

Caregiver and child demographic variables were not significantly associated with children's self-reported PTG at T1 and T2. Table 2 presents correlations among variables of interest. Contrary to expectations, self-system variables, namely perceived competence, future expectations, and coping competency beliefs, did not evidence a significant positive association with PTG at T1. In fact, perceived competence was significantly negatively related to PTG. At T2, among self-system variables, only children's future expectations showed a trend toward a positive association with PTG. Children's realistic control expectations were not significantly associated with T1 or T2 PTG scores. As expected, both intrusive and deliberate rumination were positively associated with children's PTG at T1 and T2. Caregiver warmth was positively associated with children's coping competency beliefs and future expectations, but not with perceived competence or PTG. The provision of coping advice involving positive reframing was the only caregiver variable significantly associated with T1 PTG. Contrary to expectations, no caregiver variable was significantly associated with T2 PTG.

Correlates of PTG

The hierarchical regression analyses revealed that, contrary to expectations, coping advice involving positive reframing was not significantly associated with PTG at T1, after including intrusive and deliberate rumination (see Table 3). Although perceived competence was negatively associated with PTG, it did not reach significance in the final model. Finally, as expected, deliberate rumination was related to higher PTG scores. Analyses not shown found that the inclusion of T1 PTSS did not change the pattern of associations.

At T2, after adjusting for T1 PTG and caregiver distress, although they approached significance ($p = .066$), children's future expectations were not significantly associated with T2 child PTG scores in the final model (Table 4). Moreover, intrusive rumination, rather than deliberate rumination, was associated with higher PTG scores. The inclusion of T2 PTSS minimally altered the results obtained, such that future expectations reached significance in the final step. However, because of the overlap (both conceptual and statistical) between PTSS and intrusive rumination, and in the interest of building the most parsimonious model, T2 PTSS was not included in the final model presented here. Neither age nor the age-related interactions contributed meaningfully to the regressions at either time point.

Discussion

This study sought to extend the research base on PTG in children, examining the role of child self-system and cognitive variables, as well as the caregiving context, in the youngest sample in the PTG literature. These children and their families, impacted by Katrina and its aftermath, were exposed to extreme levels of adversity, and the children evidenced negative consequences 1 year post-disaster (Gil-Rivas et al., 2010). In addition to ongoing distress, a sizable proportion reported PTG (Kilmer et al., 2009). Overall, although conclusions about causality are not possible, results suggest that rumination, both negative, distressing thoughts and deliberate, repetitive thinking, may play a key role in PTG.

Age related neither to PTG nor to the child variables assessed, a result that probably reflects the sample's restricted age range. Given that prior age-related findings have varied (e.g., Cryder et al., 2006; Milam et al., 2004), future studies could examine the degree to which variables hypothesized to be relevant to the PTG process have a differential impact across developmental stages (Kilmer, 2006).

Hypotheses involving self-system functioning, operationalized by perceptions of one's competence, coping competency beliefs, and future expectations, received minimal support. For instance, consistent with hypotheses, positive future expectations were identified as a potentially "active" variable. Specifically, although not meaningfully related to T1 PTG, after adjusting for T1 PTG and caregiver distress, future expectations at T1 approached significance in contributing to the prediction of T2 PTG in the final regression. Although the T2 finding is suggestive, these results involving future expectations are largely not consistent with adult PTG findings regarding the influence of optimism (Linley & Joseph, 2004) or child resilience research (Werner & Smith, 1982; Wyman et al., 1993). Overall, while associations involving this variable demonstrated expected relations with other self-system variables at T1, such that optimistic views about one's future

correlated with perceived competence and coping competency beliefs, it is not possible to ascertain (a) whether these expectations anteceded or were elicited by the other self-system competencies assessed, or (b) of more salience here, their specific role in the PTG process. Wyman et al. (1993) found that positive future expectations reported by 9- to 11-year-olds seemingly promoted ongoing positive adaptation, both directly and by moderating the adverse effects of subsequent stress exposure. However, following a trauma of Katrina's magnitude, as well as the persistent secondary adversities experienced by families, it may have been difficult for the children to maintain hope and optimism about their future. Nevertheless, it is possible that such future views may facilitate not only positive adaptation but also growth. That is, hope for the future may provide a lens through which children can try to view, cope with, and make sense of their circumstance, perhaps increasing the likelihood that they will try to identify the positive in their situation. Future research can address their potential role in the PTG process.

The hypothesis that the study's other self-system variables would relate positively to PTG was not supported. Specifically, in contrast to expectations and results linking competency beliefs and PTG reported by Cryder et al. (2006), a study that also included older children, coping competency beliefs did not relate to PTG at T1 or T2. Perhaps more notably, perceived competence related negatively to PTG at T1 (both at the bivariate level and in the regression, although not in the final model) and did not contribute to predictions of PTG at T2. Variables reflecting perceived competence have discriminated sensitively between those evidencing resilient adaptation and those experiencing adjustment problems (Hoyt-Meyers et al., 1995). The present findings may thus point to another point of divergence in the resilience and PTG processes. That is, the same self-views of competence that seemingly help forestall dysfunction in the face of adversity may very well reduce the likelihood of growth posttrauma. Put another way, perceptions of one's competence may foster positive adjustment, but not PTG. If one holds positive views of his or her competence, it is possible that he or she may appraise the event and its impact for him- or herself and his or her world differently; as such, these children may not perceive their assumptive worlds as "shattered" to the same degree. In turn, it may be that those children who reported more positive self-views regarding their competence may experience less distress and reduced levels of intrusive ideation and, consequently, given the presumptive link between distress and PTG, not go through a growth-like process. This notion is supported by the significant negative correlations between perceived competence and both intrusive rumination and T1 PTSS in this sample. On the other hand, if one is experiencing high levels of PTSS, as well as intrusive rumination, perhaps one path to adaptation is via deliberate, constructive rumination and PTG. The PTG evidence base has not yet established if those reporting PTG also evidence proportionally fewer PTSS over time (e.g., Salter & Stallard, 2004); however, this will be a consideration for future longitudinal examinations. Alternatively, it may be that the self-system, more globally, and competency beliefs, in particular, become more salient as children progress along their developmental trajectories and their self-views crystallize, while other factors, such as the role of the caregiver, carry special weight for younger children.

Indeed, future research will need to elucidate the role of caregivers in fostering PTG in children, because the present findings are mixed. Although caregiver warmth correlated positively with two of the study's three self-system variables (coping competency and future expectations), it did not relate to PTG. Although unexpected here, this finding is consistent with the results of Cryder et al. (2006). In considering these findings, it may be that, analogous to the results involving perceived competence, caregiver warmth and responsiveness may serve a protective function under adverse conditions (Luthar et al., 2000; Masten & Coatsworth, 1998) but may reduce the likelihood of PTG. Warm, supportive caregiving may affect youngsters' appraisal of the trauma and reduce the degree to which they feel shaken in its aftermath, thereby limiting the experience of ongoing distress thought so critical to the PTG process.

That caregiver distress did not relate significantly to the core child variables was also unexpected (though the correlation with T2 PTG approached significance). This factor is presumed to relate to availability and the capacity to provide support and nurturance, even coping advice. The present data do not convey the degree to which children were aware of caregiver distress; it may be that this factor holds salience when children perceive and understand caregivers' reactions and difficulties. This notion may also explain the lack of association between caregiver and child PTG. That is, if children are unaware of positive changes experienced by caregivers, they may not be influenced by them. It may be that such positive changes—or the orientation to seek the positive in a difficult situation—manifest in the coping guidance offered by caregivers. Notably, among the caregiver variables, only positive reframing coping advice was associated with PTG at T1, although it did not reach significance in the final model; it also did not relate to T2 PTG. The process of encouraging one's child(ren) to identify the positive in their new circumstance would appear to be of direct conceptual relevance to PTG, and the present data—including positive associations with deliberate rumination and caregiver PTG—are suggestive. The role of this variable warrants attention in future research.

Realistic control, thought to be a key cognitive resource for children, also did not function as expected. In fact, this slightly modified version of a scale used by Hoyt-Meyers et al. (1995) did not hold up psychometrically in the present sample, leading to the exclusion of the subscale for uncontrollable events. While its modification may have contributed to the scale's reduced psychometric properties, this outcome was unexpected, particularly since, as Wyman (2003) noted, the Hoyt-Meyers study demonstrated that many children in their young cohort (aged 7–9 years) had the cognitive capacity to report differentiations regarding the controllability of the events assessed. That this measure performed so poorly raises the possibility that, given the youngsters' experiences and belief systems, and the values and practices of their culture(s), the items on these scales took on a different meaning in this postdisaster context. Beyond that, the controllable subscale correlated negatively with intrusive rumination and T1 PTSS, indicating that more accurate views about controllable events tended to be associated with lower levels of intrusive thinking and PTSS. Nevertheless, realistic control did not contribute reliably to prediction models. Future research will have to examine the role of this construct in PTG.

The most noteworthy findings center on rumination. Consistent with predictions, T1 deliberate rumination related positively to PTG, after accounting for caregiving and self-system variables. In fact, this variable was the lone significant predictor of PTG in the final T1 model. In addition, T1 levels of intrusive rumination, but not deliberate rumination, significantly predicted PTG at T2, providing partial support for the hypothesized role of rumination. Although T1 levels of deliberate rumination correlated with PTG at T2 ($r = .35$), this variable did not add meaningfully to the regression model. Overall, in line with PTG theory, variables reflecting ruminative processing exhibited strong relations to growth. The present findings highlight the two complementary cognitive processes hypothesized to be at play: (a) negative, distressing ideation associated with one's ongoing struggle with adversity and his or her new reality seemingly catalyzes the process leading to growth, and (b) deliberate rumination serves a constructive function, as one works to reprocess the trauma and its aftermath, in an effort to understand and reconcile the experience with prior models of self, others, and the world. The present design cannot test these notions directly, but its results are suggestive.

That ruminative thinking was directly associated with PTG is consistent with findings reported in adult research (Linley & Joseph, 2004), but does not accord with the findings of Cryder et al. (2006)—these researchers did not examine intrusive and deliberate rumination separately and did not detect an association between rumination and PTG; rather, rumination related significantly to competency beliefs, which were associated with PTG. This study's hypotheses regarding the weight of rumination were informed by assumptions about the importance of cognitive reprocessing of the trauma to PTG, as well as the still-emerging representational worlds and self-systems of young children. It may be that the roles of self-system and rumination variables vary by age. This possibility, and the nature of the rumination–PTG relation, will need to be clarified in subsequent work. Given developmental considerations in the study of rumination (see Sprung, 2008), future studies should examine these processes in relation to PTG, in particular the constructive, cognitive reprocessing of one's circumstances, in larger, more diverse samples.

Study Limitations, Contributions, and Future Directions

Several study limitations bear mention. The study's relatively small sample affected power, prohibited the use of other statistical techniques, and limited foci to the variables selected. In addition, the sample's voluntary nature limits generalizability because nonrandom factors may have influenced families' decisions to participate. Moreover, sample characteristics (i.e., evacuees, residents of FEMA-provided housing) also limit generalizability. Other aspects of the sample's composition and cultural context may also have impacted results. For instance, the sample largely includes African American children from impoverished backgrounds, many of whom may have had significant prior trauma exposure (e.g., Osofsky et al., 2007), factors that may have influenced their post-Katrina response (e.g., appraisals and attributions), capacity (or willingness) to access services and supports, and adaptation. In addition, many evacuee children (likely including study respondents) had been attending underperforming schools and/or had been assessed as performing below national grade-level norms (Osofsky et al., 2007; Snider, Hoffman, Littrell, Fry, & Thornburgh, 2010); these factors are relevant in light of the cognitive components of the hypothesized PTG process and may influence generalizability. These results highlight future directions for child PTG research, including work investigating the function of context (Kilmer et al., 2009). Finally, that T1 was 1 year postdisaster restricts the degree to which one can draw clear temporal inferences regarding the roles of the factors associated with PTG. That is, it is unclear if they were resources or approaches present pretrauma versus "products" that increased, emerged, or evolved in the trauma's aftermath. Prospective-longitudinal designs are necessary to enhance understanding of the PTG process.

Nevertheless, the child PTG literature is nascent in its development, and the present findings contribute to the knowledge base in an area in which, to date, there has been a paucity of empirical work. Notwithstanding the limitations described, this work provides an examination of child and caregiving context variables among young children who had been exposed to severe trauma and highlights key correlates of PTG. In the early years of a developing area, it is critical to identify factors associated with the construct or process of interest. Such generative work can then be built upon with the use of methodologies that allow for exploration of the pathways seemingly involved in the growth process. The present findings demonstrate the merit of studying variables reflecting child resources and processes (e.g., rumination) and the caregiving environment in the context of PTG work and serve to identify factors that might profitably be incorporated into designs in which causal inferences are possible.

In addition, because the domains in which children evidence growth may vary with age, future efforts could compare the nature of PTG across different stages, that is, the degree to which there is a developmental progression in the manner in which PTG manifests. It may be that young children can more easily experience and express growth around their perceptions of their strength, their relationships, and their spirituality (particularly if caregivers have invoked faith-based explanations and/or encouraged faith-based coping), rather than describing a changed philosophy of life or a sense of new possibilities. Some of these presumed differences stem from the cognitive demands and self-awareness necessary to experience PTG, as well as the fact that children's sense of self is evolving and self-schema are less crystallized, thereby likely limiting the degree to which young children will describe growth in these areas. Future research could also explore the degree to which the PTG process (or one's growth trajectory) may differ following acute versus chronic traumas, or traumas with significant postevent adversities. Efforts investigating such questions could yield findings of relevance to those working in trauma, developmental psychology, and developmental psychopathology.

In addition to its heuristic benefit, research enhancing understanding of the PTG construct and the growth process among young people can yield valuable information for those working with youth who have experienced trauma (Kilmer, 2006). For example, although the present findings must be considered preliminary, they suggest the potential benefit of working to restructure youngsters' cognitive appraisals of trauma and foster productive rumination. Work in this area can also increase the likelihood that clinicians and other professionals will attend to and assess relevant competencies and resources, and take steps to facilitate resources and processes that may foster PTG (Kilmer & Gil-Rivas, 2008; Tedeschi & Kilmer, 2005).

The study examines group and individual differences in psychological functioning and hypothalamic–pituitary–adrenal and sympathetic nervous system (SNS) activity among adolescents displaced by Hurricane Katrina and living in a U.S. government relocation camp ($n = 62$, ages 12–19 years) 2 months postdisaster. Levels of salivary cortisol, salivary alpha-amylase, depression, anxiety, distress, aggression, and self-esteem for this group were contrasted with a demographically matched no-trauma control group ($n = 53$). Results revealed that hurricane exposure and SNS activity moderated the relations between lower cortisol and higher internalizing behaviors. Sex-related differences were observed in behavioral adjustment and stress regulation. Implications of sex differences in biobehavioral adjustment to loss, displacement, and relocation are discussed in relation to evolutionary and developmental theory.

In all cultures in which it has been studied, exposure to and social and material losses resulting from natural disasters is associated with increased prevalence of severe psychological distress (e.g., Chae, Kim, Rhee, & Henderson, 2005; Weinstein, Lyon, Rothman, & Cuite, 2000). Patterns of physiological and psychological reactions to natural disasters, however, may vary with the severity and duration of the attendant losses and by normative sex-related differences in biological, social, and behavioral concomitants of the stress response (Geary & Flinn, 2002; Taylor et al., 2000; Vigil, 2009). In both sexes, short-term physiological responses to acute stressors include (a) increased activation of the hypothalamic–pituitary–adrenal (HPA) axis, and the synthesis and secretion of glucocorticoids (i.e., cortisol) and (b) activation of the sympathetic nervous system (SNS) and release of catecholamines (i.e., norepinephrine, epinephrine) into the bloodstream (e.g., Chrousos & Gold, 1992). In contrast, repeated and chronic stress exposure is associated with low or blunted HPA activity (e.g., low cortisol levels or flat-shallow diurnal pattern of cortisol production), potentially reflecting habituation or adaptation to these circumstances and the overall dampening of HPA reactivity (e.g., Burke, Fernald, Gertler, & Adler, 2005; Flinn, Quinlan, Turner, Decker, & England, 1996; Miller, Chen, & Zhou, 2007).

Contemporary theorists speculate that individual differences in HPA axis activity may play a role in why exposure to adverse events results in major psychological disturbances for some individuals but has minimal consequences for others (e.g., Ellis, Jackson, & Boyce, 2006). Individual differences in HPA activity are correlated with internalizing problem behaviors (e.g., low mood), low levels of control-related beliefs, and anxiety during adolescence (e.g., Granger, Weisz, McCracken, Ikeda, & Douglas, 1996; Klimes-Dougan, Hastings, Granger, Usher, & Zahn-Waxler, 2001). These patterns can sometimes result in prolonged symptoms of posttraumatic stress disorder (PTSD) and major depression disorder, specifically, disassociation, emotional numbness, intrusive and distressful thoughts, and feelings of hopelessness, fatigue, idiopathic (cause unknown) pain, and negative self-evaluations (e.g., Ehlert, Gaab, & Heinrichs, 2001). Repeated activation of HPA and SNS has also been linked to higher morbidity, including changes that may induce

---

lower immune functioning, increased susceptibility to viral infection, and actual onset of certain diseases (e.g., pulmonary constriction; Cohen et al., 1998; Flinn & England, 2003; Kunz-Ebrecht, Mohamed-Ali, Feldman, Kirschbaum, & Steptoe, 2003; Misra et al., 2004; Rotton & Dubitsky, 2002; Segerstrom & Miller, 2004; Uchino, Cacioppo, & Kiecolt-Glaser, 1996).

Recent laboratory studies show that relations between HPA activity and some health-related consequences such as mood disturbances may in turn be moderated by SNS (e.g., El-Sheikh, Erath, Buckhalt, Granger, & Mize, 2008; Gordis, Granger, Susman, & Trickett, 2006). Bauer, Quas, and Boyce (2002) proposed that the influences of the SNS and HPA axis on child adjustment may be conditional upon one another and put forth two testable hypotheses (Bauer et al., 2002). The first hypothesis is based on an "additive" model that assumes HPA activity primarily augments (i.e., operates in parallel with) the SNS, such that symmetrical activity across these systems could result in hypoarousal (low SNS and HPA activity) or hyperarousal (high SNS and HPA activity), and prolonged psychophysiological changes in either direction may leave children susceptible to adjustment problems. Conversely, children would be at least risk for adjustment problems when both systems are only moderately active, or when the activity of the SNS and HPA is asymmetrical (i.e., one is high and the other is low). The second hypothesis is based on an "interactive" model that rests on the possibility that HPA and SNS have different functions, and HPA activity, for example, may manifest differently (e.g., behaviorally) or perhaps suppress (counteract) SNS activity. Based on this hypothesis, HPA may modulate the SNS, and asymmetrical activation of these systems would be associated with more pronounced distress behaviors (e.g., depression and/or aggression), and hence greater psychological impairment. Both models assume that homeostatic (medium) levels of arousal are optimal for wellness, and indeed numerous studies have shown that both low and high arousal levels are associated with adjustment problems (e.g., Kagan, Snidman, Arcus, & Reznick, 1994). It is important to note that both additive and interactive models, as proposed by Bauer et al. (2002), are compatible with *statistical interactions* between the systems; that is, the association between the activity of one system and child adjustment is conditional upon activity of the other system.

Gordis et al. (2006) presented the first empirical investigation of the interaction between HPA (cortisol) and salivary alpha-amylase (sAA), which is a surrogate marker of SNS reactivity (Granger, Kivlighan, El-Sheikh, Gordis, & Stroud, 2007; Rohleder, Nater, Wolf, Ehlert, & Kirschbaum, 2004), as a predictor of aggressive behavior in a sample of early adolescents. Results provided partial support for the "additive" model. Specifically, at low levels of sAA activity, lower cortisol levels were associated with higher parent ratings of aggression, but at high levels of sAA activity, lower cortisol levels were not associated with aggression (Gordis et al., 2006). That is, the highest levels of aggression were found among adolescents with low levels of both cortisol and sAA activity (i.e., symmetrical activity). More recently, El-Sheikh et al. (2008) reported interactions between basal SNS (i.e., as measured by skin conductance and sAA) and cortisol levels, and variance in children's externalizing and internalizing problems (El-Sheikh et al., 2008). Higher basal cortisol levels were positively associated with higher internalizing and externalizing problems among children with higher SNS activity, compared to children with lower SNS activity. In contrast, a recent study among toddlers found partial support for the interactive or specialization model such that sAA was more predictive of positive affect and approach behaviors, whereas cortisol was more predictive of low mood and withdrawal behaviors (Fortunato, Dribin, Granger, & Buss, 2008). These studies add to an emerging body of research that shows sAA and cortisol provide unique information in the prediction of individual differences in behavioral adjustment to stress of children (e.g., El-Sheikh et al., 2008; Gordis, Granger, Susman, & Trickett, 2008; Nater et al., 2006; Stroud et al., 2009). Moreover, this research suggests that inclusion of information about the coordination between HPA and SNS activity may be particularly important for biosocial models of risk and resilience in development science.

All studies to date, however, have only explored sAA and cortisol in relation to problem behavior using acute stress reactivity paradigms among nontraumatized samples in laboratory settings (but see research on maltreated children; Gordis et al., 2008). The present study is the first to examine coordination of HPA and SNS among displaced adolescents that have experienced chronic and pervasive stress caused by high levels of trauma, loss, and relocation. Specifically, we examined psychological adjustment and stress-related psychobiology of adolescents and young adults who lost their homes as a result of Hurricane Katrina, 2 months after the hurricane and several weeks after relocation to a large, semipermanent, U.S. government-provided housing camp. These individuals experienced multiple forms of severe and uncontrollable trauma, including events (e.g., loss of property) that resulted from the hurricane and flooding, as well as the hardship and uncertainty associated with relocating to an unfamiliar community and living under postdisaster conditions that present a unique suite of ongoing stressors (e.g., inadequate housing facilities) and vulnerability (e.g., isolation from friends and family) onto themselves. Previous research has shown that postdisaster relocation and economic disadvantage can exacerbate the negative psychobiological consequences of the original event (Adams, Boscarino, & Galea, 2006; Cohen, Doyle, & Baum, 2006; McFarlane, 1990; Najarian, Goenjian, Pelcovitz, Mandel, & Najarian, 2001; Pérez-Sales, Cervellón, Vázquez, Vidales, & Gaborit, 2005). These findings suggest that displaced survivors of Hurricane Katrina may be at high risk for negative health consequences and prolonged difficulties in social and economic recovery due to the severity and uniqueness of their shared chronic (prolonged) and acute (daily) stress exposure (Osofsky, Osofsky, & Harris, 2007).

The Katrina sample was compared to a demographically matched comparison group that was not exposed to the hurricane. Comparisons were made between the Katrina and control groups on symptoms of depression, anxiety, psychological distress, aggression, and self-esteem, along with noninvasive measures (in saliva) of individual differences in HPA (cortisol) and SNS activity (sAA). We choose to focus on sex differences in biosocial stress responses, because males and females show baseline differences in certain types of problem behaviors, and may correspondingly develop unique behavioral and physiological patterns for responding to distress (Vigil, 2009). In general, females present greater symptoms of internalizing behaviors, such as depression and worrying, whereas males show greater externalizing behaviors, including higher levels of physical aggression and risk taking (Crick & Zahn-Waxler, 2003; Khan, Gardner, Prescott, & Kendler, 2002; Tolin & Foa, 2006; Vigil, 2008).

In laboratory studies, in comparison to women, men often show greater HPA and sympathetic activation in anticipation of and immediately following stressful stimuli, particularly events that involve a social-evaluative component (e.g., public speaking tasks; Kajantie & Philips, 2006; Kudielka et al., 1998; Uhart, Chong, Oswald, Lin, & Wand, 2006). Other research has found that cortisol spikes immediately following a traumatic experience (e.g., measurements taken at hospital admission centers) are more predictive of boys' rather than girls' subsequent risk for developing PTSD (Delahanty, Nugent, Christopher, & Walsh, 2005). More specific analyses suggest that women's stress systems are more sensitive to social exclusion, whereas men's stress systems are more sensitive to social-competitive situations (Salvador, 2005; Stroud, Salovey, & Epel, 2002). This research suggests that males may be at greater risk for adjustment problems following traumatic events that diminish the individual's relative social standing (Flinn, 2006; Sapolsky, 2004), such as significant material losses and lowering of social status that often result from natural disasters.

From an ultimate level of analysis or evolutionary perspective, normative patterns of behavioral distress, such as sadness and worrying behaviors have been described as *functional* for modifying the individual's behaviors (e.g., lowering risk-taking behavior in states of vulnerability) or the behaviors of others in ways that increase fitness (survival and reproductive prospects; Allen & Badcock, 2003; Fournier, Moskowitz, & Zuroff, 2002; Keller & Nesse, 2005; Sloman & Gilbert, 2000). For example, Vigil (2009) recently proposed a ''sociorelational'' framework that suggests that both sexes may respond to chronic stressors with an overall shift from the expression of dominant behaviors (e.g., assertiveness, aggression, extraversion) to submissive behaviors (e.g., depression and worrying behaviors) to signal trustworthiness to others and to elicit increased social support. Distress behaviors may operate in part to consolidate (strengthen) the reliability of one's relationships to gain additional needed support during adverse life experiences (see also Hagen, 2003).

In terms of sex differences, several theorists have suggested that modern-day masculine and feminine emotive styles (e.g., higher rates of crying and comforting behaviors in females and higher aggression and risk-taking behaviors in males) may by an artifact of unique social ecologies (network characteristics) and relationship demands in which ancestral males and females evolved (Geary, Byrd-Craven, Hoard, Vigil, & Numtee, 2003; Geary & Flinn, 2002; Taylor et al., 2000; Vigil, 2007, 2009). The basic distinction between male's and female's social dynamics pivots on the quality and quantity of relationships that members of each sex typically form and the level of investment behaviors that are needed to maintain different types of social networks. According to Vigil (2009), because girls and women tend to form fewer yet more intimate and more exclusive social relationships than males, on average, they may be similarly sensitive to display their vulnerability (e.g., via internalizing behaviors) in ways that advertise their trustworthiness and demonstrate their reciprocal investment to others (see also Geary et al., 2003; Vigil, 2007). Exaggerated displays of vulnerability and appeasement behaviors may in turn operate to strengthen the formation of more intimate and reliable, yet investment-intensive, social relationships among females.

In contrast, males may be more sensitive to *relax* expressions of trustworthiness cues in favor of behaviors that demonstrate the individual's physical abilities (e.g., strength and prowess) and other dominance-related traits to others. These types of displays are more observable (e.g., flashing body movements and displayed aggression) and require less investment (e.g., time and self-disclosure) to advertise to others, and may therefore be effective for forming and maintaining larger, less intimate, and less exclusive social relationships among coalitions of males (Vigil, 2009; see also Geary et al., 2003; Vigil, 2007). Because males and females show baseline differences in externalizing and internalizing behaviors (e.g., Crick & Zahn-Waxler, 2003; Khan et al., 2002; Vigil, 2008), we therefore predicted that each sex would manifest the expected shift from dominance to submissiveness behaviors differently; for instance, that displaced males would show lower levels of aggression and displaced females would show exaggerated symptoms of depression, compared to same-sex controls.

In all, we expected the main effects of exposure group on cortisol and sAA; specifically, the Katrina sample would show physical symptoms of chronic and acute stress exposure and hence lower salivary cortisol levels and higher sAA activity, respectively. We likewise examined the hypotheses that hurricane exposure moderated the relations between cortisol activity and psychological adjustment, as well as the earlier findings (e.g., El-Sheikh et al., 2008) that sAA activity may similarly moderate relations between cortisol and psychological adjustment. We were particularly interested in the potential moderating influence of these physiological measures on sex differences for anxiety, depression, and aggression (Gordis et al., 2008). We expected females living in the relocation camp would report the highest levels of depression when compared with nonexposed females and to males in general, and expected to find stronger correlations between sAA (a proxy for acute distress reactivity) and depression for females than for males. Finally, on the basis of the hypothesized pattern for people to respond to chronic stressors with an overall shift from dominant to submissiveness behaviors, we expected the Katrina sample would report lower aggression than would the controls and, given higher baseline aggression in males in general, that this difference would be most pronounced among displaced males.

Method

Event and Setting

Hurricane Katrina struck the North-Central Gulf coast (mostly Louisiana and Mississippi) on August 29, 2005. Although structural devastation and displacement was widespread, the most populated region affected by the hurricane was New Orleans, due in part to several breaches in the levees that protected the city from the surrounding Lake Pontchartrain (Travis, 2005). In addition to the direct loss of life, injury, and structural devastation caused by the hurricane, hundreds of thousands of people were either permanently or temporarily displaced from their communities. Many of these refugees were forced to seek shelter in government and community shelters, often being transported across multiple shelter sites throughout the United States. For the most severely affected individuals and families, government sponsored relocation camps were built to provide semipermanent (i.e., indefinitely provided) housing facilities. The largest of these camps, located near the city of Baton Rouge, Louisiana, was the site chosen to conduct the present study. At the time of our data collection, the camp, referred to by the residents and wider community as "Renaissance Village," consisted of approximately 500 travel trailers, each housing an average of three people (not including infants and young children). The site included a central tent and barracks area, which served as the local post office and cafeteria and where supplies (e.g., clothing) were dispersed; several small laundry houses; and a basketball court. Meals were served three times a day; residents typically retrieved these from the central building and brought them back to their trailers to eat with their families. Despite the frequent efforts taken to provide the residents with comfortable conditions (e.g., seasonal festivities), the general mood in the camp at the time of data collection was notably low.

Participants

A convenience sample of 62 adolescents (mean age = 14.9, *SD* = 2.0 years; 42 females) were recruited from the housing camp approximately 2 months after the hurricane and 3 weeks after the relocation camp opened, from October 28, 2005 through November 2, 2005. Researchers solicited participation by introducing themselves to the residents (door-to-door) and targeting families living in the trailer units with children. Parents were then asked if they wanted to participate in the study ''Child and Family Wellness after a Major Natural Disaster''; approximately 65% of families agreed to participate. Upon debriefing, the participants were given a small monetary payment. All the participants reported having been relocated from the New Orleans region. The control sample consisted of 53 adolescents (mean age = 15.3, *SD* = 2.1 years, 29 females) recruited from residential neighborhoods in mid-Missouri, USA and selected based on characteristics (e.g., age, race, socioeconomic status [SES]) matching the Katrina participants, from August, 2006 through January, 2007.

Prospective participants were informed about the project goals and their rights, as a research participant outlined by the University of Missouri Institutional Review Board, and once written consent was obtained from the children and their parents, participants were asked to complete a psychological survey. Parents of participants were also asked to provide demographic information. The latter confirmed the Katrina and control groups were similar in terms of race (both groups were over 93% African American) and SES; parents did not differ ($ps > .10$) for years of education (between 11 and 12 years), history of government assistance (e.g., welfare, food stamps; over 67%), or for indicators of wealth; the average yearly income of both samples was between $4,000 and $6,000, with current (posthurricane) financial assets of less than $200. The adolescent participants from the Katrina and control groups were similar ($ps > .15$) in age and proportion by sex.

Psychological Measures

The survey consisted of several standardized, self-report instruments designed to measure psychological well-being and family functioning in adolescents and young adults. For some instruments, entire scales were administered to allow for a direct comparison across normative samples; for other instruments, partial scales were used that consisted of items representing the instrument's subscales (this enabled greater breadth in the assessed traits). Each of the instruments have demonstrated reliable psychometric properties in young adult populations, and many of the scales have been used with similar adolescent samples who had recently experienced a large-scale disaster (e.g., Ginexi, Weihs, Simmens, & Hoy, 2000; Kreuger & Stretch, 2003; Sumer, Karanci, Berument, & Gunes, 2005; see also Joseph, 2000; Linton & Marriott, 1996).

Aggression was assessed by 8 items (2 items from each of the instrument's subscales) from the Aggression Questionnaire (Buss & Perry, 1992); the items were scored on a 5-point scale (overall $\alpha = .72$). Anxiety was assessed by the Revised Children's Manifest Anxiety Scale (Reynolds & Richmond, 1978), which consists of 37 items (each scored as yes or no responses; $\alpha = .87$). Depressive symptoms were assessed by the Center for Epidemiologic Studies Depression Scale (Radloff, 1977); the instrument consists of 20 items and each is scored on a 4-point scale ($\alpha = .86$). Subjective psychological distress was measured with the Impact of Events Scale–Revised (IES–R; Weiss & Marmar, 1997). The instrument consists of 22 items (which were revised to refer specifically to Hurricane Katrina; $\alpha = .93$) and four-factor subscales designed to measure symptoms of hyperarousal, disassociation, intrusive thoughts, and avoidance behaviors during the past week (scored on a 5-point scale). The Rosenberg Self-Esteem Scale (Rosenberg, 1965) was used to assess self-described global self-esteem; the instrument consists of 10 items and each is scored on a 4-point scale ($\alpha = .73$). Completion of the psychological measures and survey items usually took between 30 and 45 min.

Determination of Salivary Analytes

The two saliva samples were collected (immediately prior to and subsequent to completion of the survey measures) between the hours of 10:50 and 18:50 via a cotton swab version of the Salivette device (Sartstedt, Newton, NC); the samples were typically collected 60–90 min apart. Two saliva samples were collected, because of the impracticality of obtaining more collections under emergency field conditions and because they provided a more reliable means of measuring sAA and cortisol activity than single sample collections (for the implementation of similar techniques, see El-Sheikh et al., 2008). After collection, all samples were transported on ice and then stored frozen (−20 °C) at the University of Missouri until shipped overnight on dry ice to the Penn State University Behavioral Endocrinology Laboratory. They were stored frozen at −80 °C until assayed for cortisol and sAA. On the day of testing, all samples were centrifuged at 1500 g for 15 min to remove mucins.

Salivary alpha-amylase. Samples were assayed for sAA using a commercially available kinetic reaction assay (Salimetrics, State College, PA). The assay employs a chromagenic substrate, 2-chloro-*p*-nitrophenol, linked to maltotriose. The enzymatic action of sAA on this substrate yields 2-chloro-*p*-nitrophenol, which can be spectrophotometrically measured at 405 nm using a standard laboratory plate reader. The amount of sAA activity present in the sample is directly proportional to the increase (over a 2-min period) in absorbance at 405 nm. Results are computed in U/ml of sAA using the formula: [Absorbance difference per minute × total assay volume (328 ml) × dilution factor (200)]/[millimolar absorptivity of 2-chloro-*p*-nitrophenol (12.9) × sample volume (.008 ml) × light path (.97)]. Intra-assay variation (CV) computed for the mean of 30 replicate tests was less than 7.5%. Interassay variation computed for the mean of average duplicates for 16 separate runs was less than 6%. The correlation between the sAA measurements was modest ($r = .43$, $p < .01$), and correspondingly, the analyses used the average levels of the two sAA samples.

Cortisol. All samples were assayed for salivary cortisol using a highly sensitive enzyme immunoassay the U.S. Food and Drug Administration (510 k) cleared for use as an in vitro diagnostic measure of adrenal function (Salimetrics). The test used 25 μl of saliva (for singlet determinations), had a lower limit of sensitivity of .007 μg/dl, range of sensitivity from .007 to 1.8 μg/dl, and average intra- and interassay coefficients of variation of less than 5% and 10%, respectively. As expected, the correlations between the cortisol measurements were positive and strong ($r = .81$, $p < .01$) and thus the average of the two samples was used in all subsequent analyses.

Diurnal course of salivary cortisol and sAA. Both salivary cortisol and sAA show distinct and different diurnal profiles. Under normative-healthy conditions, HPA axis activity (on average) follows a diurnal pattern with cortisol levels high upon waking, then rising to a zenith within 30 min of waking, sharply declining by midday, and then gradually declining through the afternoon and evening (Kirschbaum & Hellhammer, 1989). By contrast, much less is known about diurnal variation of sAA. Recent and systematic studies with adults (ages 18–58 years) reveal sAA activity shows a pronounced decrease within 60 min after awakening and a steady increase of activity during the course of the day (Nater, Rohleder, Schlotz, Ehlert, & Kirschbaum, 2007). More specifically, Nater et al. (2007) report that sAA levels increased an average of 17% with each hour across the day. There was a quadratic curvature of the sAA change across the day, with sAA decelerating from its estimated zenith at 16:25. Noteworthy is the fact that, consistent with findings regarding acute stress reactivity, the pattern of production of sAA and cortisol across the day were uncorrelated. To the best of our knowledge, there are no studies of puberty-related differences in the sAA diurnal rhythm.

Data Analysis

Missing values for either of the two cortisol or sAA measures (3%) were replaced by the other; missing values for the psychological variables (7%) were replaced by the sample means for each sex. Preliminary analyses revealed that the participant's cortisol levels were positively related to his or her awakening time ($r = .23$, $p < .01$) and negatively related to collection time ($r = -.39$, $p < .01$). Cortisol was also positively related to participant's age ($r = .21$, $p < .05$), which may be a proxy for body mass. To help control for these factors, wake time, collection time, and age were entered as covariates (for analyses of covariance [ANCOVAs] and multivariate regressions) or were partialed out (for bivariate correlations) for all analyses involving cortisol. In contrast, wake time, collection time, and age were not related to sAA, and were thus not controlled for analyses using this analyte. Among the self-report measures, only psychological distress was related to wake time ($r = -.18$, $p = .06$) and collection time ($r = .19$, $p < .05$); these variables were therefore controlled for analyses that included symptoms of distress. The Katrina and control samples did not differ for wake time or saliva collection times ($ps > .23$); however, females reported a significantly later wake time than males, $t(113) = -3.79$, $p < .01$. Groups were compared using ANCOVAs; group differences are expressed as effect sizes (*d*s; mean difference/mean standard deviation). Multivariate correlations and descriptive plots were conducted using regression analyses.

Results

Group Differences in Psychological Functioning, Salivary Cortisol, and sAA

Table 1 shows the mean psychological and salivary scores for the Katrina and control groups separately for males and females, as well as the intervariable correlations for the entire sample. Two-way ANOVAs, using sex (males vs. females) and group (comparison vs. Katrina) as predictors for each of the psychological variables revealed significant Sex × Group interactions for depression, $F(1, 111) = 4.46$, $p < .05$, and aggression, $F(1, 111) = 6.15$, $p < .05$, and a trend for a significant interaction term for distress, $F(1, 109) = 3.51$, $p = .06$, but not for anxiety ($p = .21$) or self-esteem ($p = .47$). Follow-up regressions revealed that the interaction for depression emerged due to elevated depression scores for Katrina females compared to control females ($\beta = .32$, $p < .01$, $d = -0.68$), whereas no group difference for depression was found among males ($\beta = -.08$, $p = .61$, $d = 0.16$). In contrast, the interaction for aggression was due to lower aggression scores for Katrina males compared to control males ($\beta = -.55$, $p < .01$, $d = 1.31$), whereas no group difference for aggression was found among females ($\beta = -.13$, $p = .29$, $d = 0.26$). A main effect of sex was also found for self-esteem, $F(1, 111) = 4.58$, $p < .05$, $d = -0.36$, indicating lower self-esteem among males in both groups, compared to females. The Katrina group had significantly lower cortisol levels than the control group, $F(1, 108) = 5.74$, $p < .05$, $d = 0.41$; the main effect of sex and the Sample × Sex interaction term were not significant ($ps > .10$). Neither the interaction term nor the main effect terms for group or sex were significant for sAA ($ps > .19$).

Interactions Between sAA and Cortisol Levels and Psychological Functioning

Collapsing across sex, regression analyses were used to examine the relations between sAA and the psychological measures for the comparison and Katrina groups, and between cortisol and the psychological measures for both groups. For the sAA equations, each of the psychological measures was entered as the dependent variable, and the group, sAA, and Group × sAA interaction term were entered as independent variables. For the cortisol equations, group, cortisol, and the Group × Cortisol interaction term were entered as independent variables; wake time, collection time, and age were entered as covariates. The sAA analyses revealed a trend for a significant Sample × sAA interaction term for depression ($\beta = .33$, $p = .10$) and was due to a small negative relation between higher sAA and lower depressive symptoms for the control group ($\beta = -.29$, $p < .05$), but not for the Katrina

Table 1

Group Differences and Correlations for the Psychological and Salivary Analyte Variables

	Males		Females		Sample differences		Sex differences		Correlations

Note. Values are mean scores; values in parentheses are standard deviations. Italicized values indicate significant ($p < .05$) sample differences across males or females. Group differences for distress were computed by entering collection time and wake time as covariates; group differences for cortisol were computed by entering collection time, wake time, and age as covariates. Partial correlations were computed for distress (controlling for collection time and wake time) and for cortisol (controlling for collection time, wake time, and age).

$^{\dagger}p < .10$. $^{*}p < .05$. $^{**}p < .01$.

group (β = .02, $p = .88$). The cortisol analyses revealed significant Group × Cortisol interaction terms for self-esteem (β = .47, $p > .01$), anxiety (β = .33, $p > .05$), and distress (β = −.34, $p > .05$), and a trend for an interaction for depression (β = −.31, $p = .06$). Follow-up regressions revealed that the interactions for self-esteem and anxiety were due to small positive relations between cortisol and self-esteem (β = .36, $p < .05$) and between cortisol and anxiety (β = .26, $p = .09$) for the Katrina group, and a small negative relation between cortisol and self-esteem (β = −.26, $p = .09$) for the control group; the relation between cortisol and anxiety was not significant for the control group ($p = .64$). In contrast, the interactions for distress and depression were due to small positive relations between cortisol and distress (β = .39, $p < .01$) and between cortisol and depression (β = .26, $p = .09$) for the control group, and nonsignificant relations for the Katrina group (*p*s = .78 and .21, respectively).

Collapsing across groups and sex, regressions were then used to examine the potential interactions between cortisol and the psychological measures for individuals with varying sAA activity levels. For these equations, each of the psychological measures was entered as the dependent variable, and cortisol, sAA, and the Cortisol × sAA interaction term were entered as independent variables; wake time, collection time, and age were entered as covariates. These analyses revealed a significant Cortisol × sAA interaction term for self-esteem (β = .43, $p < .05$) and a trend for an interaction for symptoms of anxiety (β = .33, $p = .10$); the interaction terms were not significant for depression ($p = .73$), distress ($p = .84$), or aggression ($p = .88$). Follow-up regressions revealed that the significant interaction emerged as a result a moderate positive relation between cortisol and self-esteem for individuals with sAA levels above the overall mean (β = .43, $p < .05$) but not for those with sAA levels below the mean (β = −.04, $p = .74$).

Sex Differences in the Relations Between Psychological Functioning and Cortisol and sAA Levels

Regressions were then used to examine the relations between each of the two analytes and the psychological scores, separately among males and females. For these equations, collapsing across groups, each of the psychological measures was entered as the dependent variable, and sex, the salivary analyte (i.e., cortisol or sAA), and the Sex × Analyte interaction term were entered as independent variables; wake time, collection time, and age were entered as covariates for the cortisol equations. These analyses revealed a trend for a Cortisol × Sex interaction for psychological distress, β = −.51, $p = .10$, and was due to a significant relation between higher cortisol and increased distress among males (β = .36, $p < .05$) and a nonsignificant relation among females ($p = .99$). None of the remaining main effects for cortisol, or the Cortisol × Sex interaction terms were significant. In contrast, regressions revealed a significant sAA × Sex interaction term for depression (β = 1.18, $p < .01$), and a trend for a sAA × Sex interaction for psychological distress (β = .64, $p = .06$). As shown in Figure 1, the significant interaction was due to a negative relation between sAA and depression in males (β = −.47, $p < .01$), and a trend for a positive relation between sAA and depression in females (β = .21, $p = .08$). No other effects of sAA were significant for the remaining psychological variables.

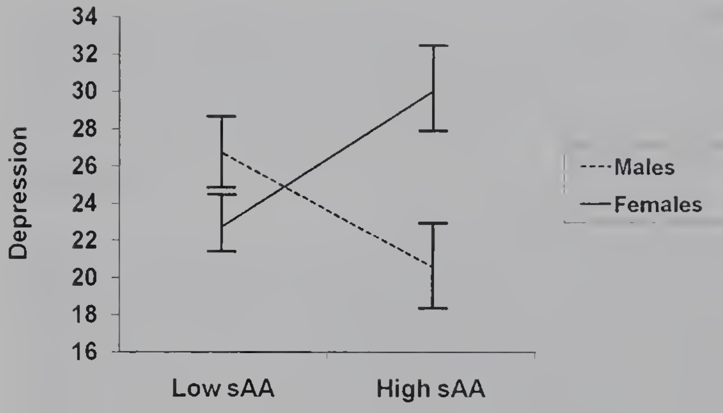

Figure 1. Plot of significant Sex × Salivary Alpha Amylase (sAA) interaction for depression. Slopes represent unstandardized regression coefficients.

Discussion

This study examined psychological functioning and concurrent cortisol and sAA activity levels in adolescents who experienced pervasive stressors resulting from significant social and material losses during and following Hurricane Katrina. In comparison to controls, both sexes in the Katrina sample showed moderately lower cortisol levels and slightly higher sAA activity; however, these differences were more pronounced among displaced females. The finding of lower cortisol among the displaced youth is consistent with other studies showing that chronic stress exposure is associated with blunted cortisol activity, potentially reflecting a general habituation or desensitization of this stress response (Flinn et al., 1996; Miller et al., 2007). Higher sAA activity (reflecting more acute stress reactivity) among the Katrina youth may reflect group differences in daily stressors, such as the temporary housing facilities and the lack of security that were the basis of common complaints from the Katrina youth.

Our findings revealed that hurricane exposure moderated the relations between cortisol activity and psychological adjustment; however, these effects were small and variable and should therefore be considered preliminary findings. Future research should benefit from more detailed theoretical models that differentiate the influences of HPA activity on different aspects of internalizing behaviors, including the respective roles on self-esteem, depression, and symptoms of anxiety, among individuals who have experienced differing levels of stress exposure. We also found support for the hypothesis that sAA moderates the relation between cortisol and internalizing behaviors; lower cortisol was associated with lower self-esteem, but only among individuals with above average sAA reactivity. This finding complements recent laboratory studies (e.g., Fortunato et al., 2008), and suggests that individual differences in HPA axis activity and psychological functioning may be associated with differential sensitivity or functioning of the SNS. Overall, however, the results are most compatible with a modified version of Bauer et al. (2002) interactionist model (p. 106), and suggest that individuals with high sAA activity and low cortisol may be at greater risk for mood problems, whereas high sAA combined with high cortisol may be associated with psychological resiliency.

In terms of sex differences, and consistent with research among normative (nontraumatized) adolescents (e.g., Ge et al., 2003; Rushton, Forcier, & Schectman, 2002; see also Vigil, 2008), the females in our study reported higher symptoms of depression than did the males. Individuals of both sexes and in both groups reported higher levels of depressive symptoms than are found in normative samples (e.g., see Brooks & Kutcherm, 2001, p. 365), but these symptoms were particularly high among the Katrina females. The pattern is consistent with a sociorelational perspective of distress behaviors, and the evolutionary hypothesis that people in general, and especially females, may respond to negative life events with behaviors that exaggerate the displays of vulnerability and increase the perception of trustworthiness to other people (Vigil, 2009). From this perspective, certain types of behavioral distress (e.g., worrying, crying, feelings of hopelessness) may be functional for consolidating one's social network and evoking increased emotional support from intimate confidantes (e.g., family members and close friendships), in coordination with adverse life experiences. These are the types of events that demand the greatest social support from others, and behaviors that explicate individual vulnerability may be particularly effective for evoking dependable and continuous forms of investment from others (Vigil, 2009; see also Hagen, 2003).

Females may be particularly sensitive to display cues of trustworthiness (e.g., via sadness behaviors) and to emotionally invest in their relationships (e.g., via comforting behaviors), compared to males, because these behaviors were beneficial for maintaining more intimate and exclusive dyadic relationships (e.g., see Geary et al., 2003; Vigil, 2007, 2009; see also Geary & Flinn, 2002; Taylor et al., 2000). Females may be particularly vulnerable during adolescence and reproductive maturation and especially in situations of unreliable social support; these are conditions that can result in sexual exploitation and pregnancy. Adolescence is a time when sex differences in the display of trustworthiness cues (e.g., via sadness behaviors) are predicted to emerge, and to function to maintain social-support systems (see Del Giudice, 2009; Geary et al., 2003; Vigil, 2009). This hypothesis is consistent with research on depression during adolescence that shows that symptoms tend to increase in females, but not males, between 12 and 13 years in U.S. samples (e.g., Ge, Conger, & Elder, 2001; Ge et al., 2003). Likewise, recent research shows a relation between HPA activity and intimate relationship dynamics (e.g., quality of relationships) in adolescent females, but not females in middle childhood, or males of either age group (Booth, Granger, & Shirtcliff, 2008).

Reported levels of aggression were similarly higher than that found in normative samples for all groups (Archer, Kilpatrick, & Bramwell, 1995, p. 376), except the Katrina males. Aggression for these males was in the normative range but substantially lower than that reported by the control males or by females of either group. Although counterintuitive, this finding was predicted based on higher normative (no-trauma) levels of aggressive behaviors in males in difficult circumstances and the hypothesis that people respond to chronic, noninterpersonal victimization, stressors with decreased dominance and increased submissive behaviors (Allen & Badcock, 2003; Fournier et al., 2002; Sloman & Gilbert, 2000; Vigil, 2009). Similar patterns emerge in male primates under chronic stress and following loss of status (Sapolsky, 2004, 2005). From a sociorelational perspective, aggressive behaviors may be similarly interpreted as a form of social behavior that may be more adaptive for males than for females under normal (no-trauma) conditions but are associated with added costs when males experience events that decrease their social status or the ability to protect themselves (Vigil, 2009).

Another possibility for our finding of relatively lower aggression in affected males may be that the males in this study are unrepresentative of more general samples; males willing to accept government assistance may be less aggressive than displaced males who are not living in a relocation camp. Lower aggression among displaced males may also reflect environmental rather than conditional or individual differences. For example, the Katrina camp environment may be more mundane than the environment in which the Katrina males were situated prior to the hurricane or in comparison to the acute stressors (e.g., overcrowding conditions at the Superdome, temporary disaster facility), immediately following the hurricane. In any case, males are more sensitive to changes in social standing than are females (Geary, 1998), which may explain our finding of the stronger concordance between cortisol and symptoms of psychological distress in males than among females (for similar results, see Delahanty et al., 2005).

Finally, the results support the hypothesis that sex moderates the relation between sAA and symptoms of depression, such that higher sAA among the youth in both groups was related to lower symptoms of depression (e.g., greater confidence and reported elation) in males and slightly higher depressive symptoms among females. The findings are consistent with a recent study that showed that sAA is distinctly associated with positive affect and overall approach behaviors (Fortunato et al., 2008), and research indicating normative sex differences in behavioral reactivity (i.e., to respond to mild stressors with more externalizing vs. internalizing behaviors; Vigil, 2008). Moreover, our findings suggest that sAA may be a promising marker for identifying depressive symptoms in adolescents, but they are qualified by the collection of only two saliva samples. It is possible, for instance, that sAA activity may follow a diurnal rhythm (see findings by Nater et al., 2006) similar to patterns observed in cortisol. Still, we found no evidence for such a pattern of sAA in our study using controls for the independent influence of collection time and awakening time. Systematic studies are needed to examine the effectiveness of sAA for measuring symptoms of depression among children exposed to ordinary and extraordinary stressors.

Limitations

Future research on individual and group differences in stress responses following large-scale disasters will benefit from addressing specific constraints in the design of these studies. For example, although the window of time we used to collect the saliva samples was reasonable under the constraints of our field study, the use of practical saliva collection techniques that enable researchers to track hormonal fluctuations in the morning and across the day under emergency field conditions is needed. This research is particularly complicated when working with transient families and individuals with low education, as was the case in the current study. It was unfortunate, although understandable, that pre-trauma information was not available, particularly for baseline physical or mental health, and non-trauma-related stressors in either the Katrina or the control group. It would have also been helpful to have been able to examine the role of pubertal timing, especially among females, for examining more specific hypotheses from the theoretical models. The current study was also limited by the small sample size and homogeneous characteristics (e.g., low SES) of our samples. Future research will benefit from assessments of psychological functioning of males and females from representative samples that include adolescents with diverse family and socioeconomic backgrounds. Additional limitations were the single source (self-report) of data collection, lack of information on current illnesses and medication use, and the relatively wide age range of participants that were assessed. It is certainly possible that children undergo systematic psychological and physiological changes that may operate in conjunction with distinct psychoneuroendocrine and behavioral patterns of stress response, at different stages of development (e.g., see Vigil, 2009).

Despite these limitations, the study contributes to our understanding of normal psychobiological distress in males and females, and it is the first study to demonstrate sex differences in psychological functioning and salivary cortisol and sAA activity among adolescents that have experienced pervasive stressors that included significant disruptions in social relationships and widespread loss of property caused by a major natural disaster. It is unclear at this time, however, how these types of experiences and stress recovery mechanisms may actually affect normative and long-term development. Recent laboratory studies have shown that, in comparison to younger children, adolescents may be particularly sensitive to social evaluation and stressors that reduce the individual's social standing (Booth et al., 2008; Stroud et al., 2009). Lower sociometric competitiveness caused by significant social and material losses may in turn have an exacerbating effect for adolescents already in low-resource environments. Based on our findings, such disruptions may be manifested through divergent behavioral patterns in males and females, which in theory may be associated with remedial social benefits, as well as potential mental and physical health-related consequences.

Children of Katrina: Lessons Learned About Postdisaster Symptoms and Recovery Patterns

Mindy E. Kronenberg, Tonya Cross Hansel, Adrianne M. Brennan, Howard J. Osofsky, and Joy D. Osofsky
Louisiana State University Health Sciences Center

Beverly Lawrason
St. Bernard Parish Public Schools

Trauma symptoms, recovery patterns, and life stressors of children between the ages of 9 and 18 (n = 387) following Hurricane Katrina were assessed using an adapted version of the National Child Traumatic Stress Network Hurricane Assessment and Referral Tool for Children and Adolescents (National Child Traumatic Stress Network, 2005). Based on assessments 2 and 3 years after the hurricane, most children showed a decrease in posttraumatic stress and depression symptoms over time. Students were also classified into outcome trajectories of stress resistant, normal response and recovery, delayed breakdown, and breakdown without recovery (A. S. Masten & J. Obradovic, 2008). Age, gender, and life stressors were related to these recovery patterns. Overall, the findings highlight the importance of building and maintaining supportive relationships following disasters.

> *When we evacuated, I was glued to the TV watching the destruction. I asked my parents for help, but they were as bewildered as I was. I realized I had to grow up fast to be able to help myself and also support them. My father still does not have his job back. I don't know what the future holds, but after surviving Katrina, I am sure I can handle it.* (14-year-old high-school student 1 year after Hurricane Katrina)

Immediately after Hurricane Katrina struck the Gulf Coast on August 29, 2005, both physical and psychological recovery began. Hurricane Katrina has been described as one of the worst natural disasters in U.S. history (Knabb, Rhome, & Brown, 2006), and, 4 years later, it continues to impact residents and communities in Louisiana. For example, St. Bernard Parish, an adjacent parish (county) to New Orleans in which this study was conducted, was completely devastated by the hurricane with the entire region damaged by flooding and a large oil spill. At the time of this study, recovery in St. Bernard Parish had been slow with approximately 50% of the population returning to the parish (St. Bernard Parish Government, 2008) and 47% of the children returning to the schools (St. Bernard Parish Public Schools, 2008).

Disasters with a slow recovery, such as Hurricane Katrina, can result in acute and chronic psychological effects (Kessler, Galea, Jones, & Parker, 2006; H. J. Osofsky, Osofsky, Kronenberg, Brennan, & Hansel, 2009; Weems et al., 2007), which may negatively impact the child's normal developmental trajectory (Pynoos, Steinberg, & Piacentini, 1999; Shaw, 2000). Of particular interest to child development is the occurrence of large-scale traumas, such as Hurricane Katrina, which affect not only the individual but also the multiple systems, including microsystems and exosystems, in which children develop (Bronfenbrenner, 1986; Masten & Obradovic, 2008). For many children of Katrina, their once-thriving neighborhoods, grocery stores, and playgrounds were no longer functional; many children experienced multiple moves and changes in schools as well as parental unemployment (Osofsky, Osofsky, & Harris, 2007; H. J. Osofsky et al., 2009). The outcomes for these children are still under question.

This research was supported by grants from the Robert Wood Johnson Foundation and Baptist Community Ministries. Much appreciation is expressed to the trauma team in the Department of Psychiatry at Louisiana State University Health Sciences Center and to St. Bernard Parish Public Schools. We would like to acknowledge Michelle Bacon Moore and Erika L. Bocknek for their assistance with references and editing.

Traditionally, child-focused disaster research examines postdisaster symptomatology. For example, the majority of the current literature suggests that children who experience hurricanes are at a higher risk for symptoms of depression, anxiety, and posttraumatic stress disorder (PTSD; Goenjian et al., 2001; Kessler et al., 2006; J. D. Osofsky, Osofsky, Kronenberg, & Cross, 2009; H. J. Osofsky et al., 2007); however, recent theoretical research has focused on examining patterns of recovery (Bonanno, 2004; Bonanno & Mancini, 2008; Masten & Obradovic, 2008). The problem with placing emphasis only on symptoms following disasters is that the focus is on psychopathology that limits attention to the full array of recovery. By examining recovery patterns, researchers can turn their attention to the multiple outcomes that follow disasters including posttraumatic growth and continued normal development, as well as maladaptation.

This study approaches disaster research by examining not only the symptomatology endorsed by children, who have experienced Hurricane Katrina but also the recovery patterns of these children and life stressors that influence these patterns. More specifically, this study examined longer term recovery and focused on the responses provided by children in the 2nd and 3rd years following Hurricane Katrina. Variable-focused analyses examined the course of trauma-related symptoms of depressed mood and posttraumatic stress over time, whereas person-focused analyses compared groups of students in 4th–12th grades who fit theoretical patterns of recovery described in the literature as either positive or negative outcome trajectories (Masten & Obradovic, 2008). The effects of life stressors, age, and gender on the course of post-Katrina trauma symptoms and recovery patterns were also examined.

Impact of Natural Disasters on School-Age Children and Adolescents (PTSD and Depressive Symptoms)

A number of disaster studies have documented symptoms of PTSD in children who have experienced natural disasters including earthquakes, tsunamis, and hurricanes (Goenjian et al., 2005; John, Russell, & Russell, 2007; Kolaitis et al., 2003; La Greca, Silverman, Vernberg, & Prinstein, 1996; Lonigan, Shannon, Taylor, Finch, & Sallee, 1994; Piyasil et al., 2007; Pynoos et al., 1993). Many of these studies have reported comorbid symptoms of depression in children following natural disasters. Although there is overlap in symptomatology of both PTSD and depression, including anhedonia, sleep difficulties, problems with concentration, irritability, and a restricted range of affect (American Psychiatric Association, 2000), the research has been clear in demonstrating the distinct presence of each disorder following disasters (Goenjian et al., 2001; Kolaitis et al., 2003; Roussos et al., 2005). For example, a study exploring PTSD and depression in children between the ages of 7 and 17 who experienced a super-cyclone in India found that although PTSD and depression were significantly correlated, most children with PTSD did not meet criteria for depression, and 55.7% of children with a diagnosis of depression did not meet criteria for PTSD (Kar et al., 2007).

The relation between PTSD symptoms and disaster-specific aspects of trauma has been well documented in the literature. For example, a study of 16- and 17-year-old children following a 1999 earthquake in Greece (Roussos et al., 2005) as well as studies of 13-year-olds following Hurricane Mitch in Nicaragua (Goenjian et al., 2001, 2005) showed that exposure to a natural disaster was consistently related to increases in the severity of PTSD symptoms. In a study of over 5,000 children aged 9–19 who experienced displacement and damage to their homes as a result of Hurricane Hugo, PTSD was associated with traumatic experiences (Lonigan et al., 1994). Similarly, Russoniello et al. (2002) found that 9- to 12-year-old children whose homes were flooded as a result of Hurricane Floyd were three times more likely to have symptoms of PTSD compared with those whose homes did not flood. Hamada, Kameoka, Yanagida, and Chemtob (2003) reported that 6- to 12-year-old children who experienced Hurricane Iniki were more likely to report posttraumatic symptoms if they felt that their lives or the lives of others were threatened at the time of the hurricane.

Neuner, Schauer, Catani, Ruf, and Elbert (2006) assessed 64 tsunami survivors in Sri Lanka, aged 8–14, and found that previous traumas, including exposure to war, domestic violence, community violence, medical treatment, physical abuse, and natural disaster, were associated with increased posttraumatic stress symptoms. Similarly, Garrison, Weinrich, Hardin, Weinrich, and Wang (1993) assessed 1,264 children, aged 11–17, following Hurricane Hugo and found that experiencing previous violent, traumatic events was associated with increased likelihood of PTSD.

Unlike symptoms of PTSD, depression has not been found to be consistently related to the level of disaster exposure or proximity. Depression has been associated with several different factors including reported difficulties at home following the disaster (Roussos et al., 2005), death of a family member (Goenjian et al., 2001), and feeling that one's own life or the lives of family members were in danger (Thienkrua et al., 2006).

Impact of Hurricane Katrina on Children

Research data are becoming available on the effects of Hurricane Katrina on children and adolescents, and studies reflect the unprecedented scale of the storm and complexity of the recovery. In a sample of 166 students in the 9th through 12th grades, Marsee (2008) found that 63% of students had symptoms of PTSD 15–18 months following the hurricane and that the PTSD symptoms together with high levels of aggression were associated with emotional dysregulation. Weems et al. (2009) expanded the understanding of post-Katrina symptomatology finding that, among 52 children with a mean age of 11 years in the 6–7 months following Katrina, the level of posttraumatic stress symptomatology was related to hurricane exposure, female gender, and level of predisaster anxiety. Further research by H. J. Osofsky et al. (2009) found that variables including separation from a caregiver and evacuating to a shelter were associated with posttraumatic stress symptoms in 7- to 19-year-old students 2 years after Hurricane Katrina.

Scheeringa and Zeanah (2008) studied PTSD in 3- to 6-year-old children and found that hurricane-related PTSD was associated with caregiver's level of symptomatology. Spell et al. (2008), in a study of 8- to16-year-old students, found similar results, reflecting the importance of caregiver's symptomatology in predicting a child's psychological status. Terranova, Boxer, and Morris (2009) provided further support for the importance of relationships in their study of sixth grade students who evacuated for Hurricane Katrina but did not experience significant flooding. In this group of children, negative peer interactions were associated with symptoms of PTSD 8 months following the storm. Based on the newly emerging literature, PTSD following Hurricane Katrina appears common, and children's responses are associated with hurricane exposure as well as environmental and relational factors.

Impact of Age on Children's Psychological Responses to Natural Disasters

Some researchers have reported a significant association between the age of a child and the occurrence of psychopathology following disasters. For example, McDermott and Palmer (2002) reported that depression following trauma is more common in younger children than older children in a sample of 8- to 19-year-olds who experienced loss associated with a bushfire. Similarly, Shannon, Lonigan, Finch, and Taylor (1994) reported that in a sample of 5th through 11th graders impacted by Hurricane Hugo, symptoms of posttraumatic stress are more common in younger children than older children. Although these studies suggest that younger children are more susceptible to significant psychopathology following a natural disaster, some studies have indicated otherwise, and a consistent pattern of age differences in response to disasters has not yet been established (Vogel & Vernberg, 1993). A 2008 study of 8- to 15-year-old children found high levels of PTSD 3 years following an earthquake; however, child age did not impact the presence or severity of the disaster response (Bal, 2008). Another study of adolescents in the 9th through 12th grades following Hurricane Katrina demonstrated similar results indicating that age does not necessarily influence traumatic response (Marsee, 2008).

In contrast, research regarding how children express traumatic responses has been well established. Commonly observed traumatic reactions in school-age children include: specific fears, separation difficulties, sleep problems, reenactment of the trauma in play, regression, somatic complaints, irritability, decline in academic performance, fear of recurrence of the trauma, and trauma-related guilt (Steinberg, Brymer, Decker, & Pynoos, 2004; Vogel & Vernberg, 1993). Adolescents, on the contrary, express difficulties through individuation and identity development processes. Pynoos (1993, p. 222) stated that "a trauma-induced sense of discontinuity can give a disrupting influence on the adolescent task of integrating past, present, and future expectations into a lasting sense of identity." Pynoos reaffirmed Blos (1967) who described that adolescence is a period of individuation and elaborated that any threat to this process, through trauma, can potentially disrupt the developmental focus of this important period.

Impact of Gender on Children's Psychological Responses to Natural Disasters

Research on children and adolescents has generally also shown a relation between gender and reports of posttraumatic stress symptoms following exposure to natural disasters. The majority of studies have reported that females are more likely than males to develop PTSD symptoms (Bal, 2008; Giannopoulou et al., 2006; John et al., 2007; Pfefferbaum, 1997; Shannon et al., 1994). For example, following Hurricane Floyd, 9- to 12-year-old females were twice as likely as males to report symptoms of PTSD (Russoniello et al., 2002). Although much of the literature has described gender differences in psychological response to trauma, not all research is consistent on this finding. For example, Kar and Bastia (2006) reported no significant differences in depression and PTSD diagnoses for males and females in high school students following a supercyclone; however, they did report differences in the expression of symptomatology with girls being more likely to report guilt and boys more likely to have increased worry, anhedonia, concentration problems, and academic problems. Shannon et al. (1994) also described gender differences in expression of symptomatology in 9- to 19-year-old children and adolescents with females being more likely to report symptoms associated with emotional reactions and males more often showing symptoms associated with cognitive and behavioral reactions.

Effects of Natural Disasters Over Time

Research on the longitudinal effects of PTSD and depressive symptomatology following disasters indicates that, for the majority of children with PTSD or depressive symptoms, symptoms naturally decrease or remit in the months and years following the event. Vogel and Vernberg (1993) reported that following disasters, symptoms decreased rapidly, usually by 9–14 months postdisaster, and remitted within 18 months to 3 years. However, these authors noted that this recovery may not occur when there has been a severe threat to life or when there is long-term family or community disruption. In children for whom this is the case, persistence or even increases in PTSD and depression have been well documented. McFarlane, Policansky, and Irwin (1987) reported that for 5- to 12-year-old children who witnessed a bushfire, depressive symptoms increased between 2 and 8 months following the disaster and remained elevated when assessed 2 years later. Bal (2008) found that 3 years after an earthquake, high levels of PTSD among 8- to 15-year-old children were associated with chronic stress due to the destruction of housing and community infrastructure. Other studies have found that postdisaster symptoms may have a late onset. For example, John et al. (2007) found that 11% of 5- to 18-year-old children who survived an earthquake and tsunami in Asia developed delayed onset symptoms of PTSD.

Related to hurricane-specific trauma, La Greca et al. (1996) assessed PTSD symptoms in third- through fifth-grade children 3, 7, and 10 months following Hurricane Andrew and found that PTSD symptoms declined over time, although many children remained symptomatic 10 months postdisaster. Symptomatology 10 months postdisaster was related to level of exposure, demographic characteristics, other life stressors, availability of social supports, and type of coping strategies. Halpern and Tramontin (2007) commented that 40% of children who exhibited PTSD symptomatology 10 months after Hurricane Andrew remained symptomatic 3½ years later.

Bokszczanin (2007) highlighted the long-term effects of natural disasters as well as the influence of age and gender on psychological sequelae. Twenty-eight months following a flood, 18% of children ages 11 through 21 met criteria for PTSD. In this sample, the levels of PTSD symptoms were higher in both younger and older females and in younger, but not older males. The author concluded that younger children, regardless of gender, and females, regardless of age, are at higher risk for developing PTSD symptoms following a disaster; he further stated that older males are at the lowest risk of developing PTSD following a disaster.

Few studies have documented continuing symptoms 5 years or more following natural disasters. On such study by Goenjian et al. (2005) followed children after an earthquake and found that PTSD symptoms remained elevated when measured in untreated 16- to 17-year-old children at 18 months and 5 years following the disaster. In another study, data collected 2 years and again at 17 years following the Buffalo Creek Dam collapse indicated that among children who were between the ages of 2 and 15 at the time of the disaster, anxiety, belligerence, somatic concerns, and agitation decreased over time and that, overall, the majority of the sample appeared to have recovered when they were assessed 17 years later. The affected sample no longer showed an elevated level of PTSD when compared to the comparison sample with the level of PTSD decreasing from 32% to 7%. However, females were more likely than males to exhibit long-term symptoms of PTSD, and substance abuse and suicidal ideation were higher among those individuals affected by the dam collapse when compared with individuals in the comparison group (Green et al., 1994).

Overall, the literature indicates that trauma symptoms in children decrease over time (Green et al., 1994; La Greca et al., 1996; Vogel & Vernberg, 1993); however, several researchers have noted that, for some children, trauma symptoms persist (e.g., Bal, 2008; Goenjian et al., 2005; McFarlane et al., 1987). Pynoos (1993) summarized common factors associated with poor long-term outcomes following trauma exposure. He noted that disasters followed by extended periods of high cumulative adversity related to breakdown of infrastructure, ongoing economic consequences, family stress, loss of life and property, and other aspects of slow recovery pose a much greater risk to recovery and well-being.

Patterns of Recovery

Although it is important to document and follow the development and course of symptomatology following natural disasters, this approach does not fully account for the complexities of recovery patterns. Compas, Hinden, and Gerhardt (1995) highlight the importance of addressing the complex pathways to outcomes rather than individual risk or protective factors. Complex pathways include both immediate and chronic consequences of trauma as well as characteristics of the individual and the individual's social environment. Sroufe (1997) expands on this notion, describing the complexities of development following adversity by stating that pathways, including resilience and maladaptation, are not static; rather, they evolve over time and are based on previous experiences and coping capacities. Addressing complex trajectories provides an understanding of positive responses to disasters in addition to the pathological symptomatology discussed previously.

Recently, researchers including Masten and Obradovic (2008) and Bonanno and Mancini (Bonanno, 2004; Bonanno & Mancini, 2008) have focused theoretical discussions on the description of patterns of recovery following trauma. Masten and Obradovic (2008) discuss eight possible outcome trajectories in the context of disaster: *Resistance* refers to the pattern of functioning well during and following a disaster whereas *normal response and recovery* refers to a pattern of initial adaptive problems followed by recovery to good adaptive function. Maladaptive response patterns include *delayed breakdown*, which refers to resistance followed by breakdown in functioning, and *breakdown without recovery*, which refers to a maladaptive response with no improvement. Other patterns of recovery are based on the individual's predisaster functioning. Positive transformation, from either higher or lower levels of predisaster adaptive functioning, may occur following a trauma, and maladaptive patterns of predisaster functioning may continue or worsen following a disaster.

Bonanno and Mancini (2008) have discussed similar recovery patterns, which are described as resilience and recovery patterns as well as chronic and delayed dysfunction patterns. In this conceptualization, *resilience* is described as the absence of a negative response following a trauma, *recovery* is described as having an initial negative response following a trauma but recovering to adaptive functioning, *chronic dysfunction* is described as a negative trauma response that does not abate with time, and *delayed dysfunction* is described as trauma symptomatology that increases over time (Bonanno, 2004; Bonanno & Mancini, 2008).

Regardless of whether a child demonstrates resilience or maladaptation, patterns of recovery must be considered within a developmental framework and address the multiple developmental tasks that children face (Bonanno & Mancini, 2008). Pynoos et al. (1999) advocate a ''complex developmental perspective'' (p. 1542) when considering child traumatic stress and outcomes. The complexity refers to the multiple influences of child factors such as age, gender, previous experiences, and environment (Pynoos et al., 1999). The study of both positive and negative outcomes following disasters can provide more understanding of both traumatic responses and the ways that disruptions of multiple systems impact a child's development following adversity.

Purpose of Study

This study assesses the responses and symptomatology of children and adolescents from a heavily devastated area 2–3 years following Hurricane Katrina and categorizes their responses according to Masten and Obradovic's (2008) theoretical patterns of recovery. More specifically, this study focuses on the developmental factors of age, gender, and life stressors associated with multiple developmental systems and their impact on the course of post-Katrina recovery patterns. The first hypothesis is that student reports of PTSD and depressive symptoms will decrease over time and that changes in symptoms will be related to gender and age. Specifically, it is hypothesized that older children and males will be more likely to report reduction in symptomatology over time than younger children and females. The second hypothesis is that adversity and perceived life stressors will affect the classification of students' recovery patterns into one of four outcome trajectories—stress resistant, normal response and recovery, delayed breakdown, and breakdown without recovery. The third hypothesis is that age and gender will moderate the relation between the life stressor variables and outcome trajectories.

Method

As part of a larger assessment of children's overall needs after Hurricane Katrina, the current study focuses on data collected in St. Bernard Parish for the purpose of guiding the delivery of intervention services. The St. Bernard Parish School District administered the National Child Traumatic Stress Network (NCTSN) Hurricane and Assessment Referral Tool (NCTSN, 2005) to students in the schools, and faculty from Louisiana State University Health Sciences Center (LSUHSC) Department of Psychiatry was available to answer questions or provide support. Screeners were administered to students in the target community if they were in 4th through 12th grades; there were no major exclusion criteria within this group of students. The assessment was administered confidentially, but not anonymously, so that it was possible to provide further evaluation for students who scored above the cutoff for mental health symptoms and respond to those who requested a meeting with a counselor. Students were given the opportunity to refuse participation on all or parts of the screen at their discretion. Reports, including compilations of students' responses, were given to the schools in order to provide them with more information about student's concerns in an effort to improve services and enhance the school environment. This study was submitted and received approval by the IRB Board at LSUHSC.

Students were assessed each school year for mental health needs beginning immediately after Hurricane Katrina (2005–2006) and continuing to the most recent 2007–2008 school year. Given the variability of the students returning during the 1st year and the influx of students in subsequent years, Years 2 and 3 were used in the analysis. Among the total group of students, we had an approximately 67% rate of response: 1,826 surveys were returned for the 2006–2007 academic year and 1,380 were returned in the 2007–2008 academic year. Students were selected for inclusion in the current study if they were screened during both the 2nd and 3rd post-Hurricane Katrina years (n = 542). Acock (2005) indicates that attrition is a major concern in all longitudinal community-based surveys, and a 50% rate of attrition over time is common. Although the rate of attrition in the current study is higher, it is not unexpected in a post-disaster environment. Mobility rates and school absences throughout this time were high, with difficulties in housing, family illnesses or stressors, parent employment, and families moving to other locations as community recovery languished. Missing data analyses indicate that these 542 students do not differ significantly on whether or not students met the cutoff score for enhanced mental health services at Time 3 when compared with the group of 1,258, $\chi^2(1) = 1.67$, *ns*. Among those 542 students, 387 students (71.4%) provided complete data for the variables related to the research questions in the current study. Furthermore, missing data analyses indicate that the 387 students do not differ significantly from the students without complete data on all outcome variables: outcome trajectories, $\chi^2(1) = 4.22$, *ns*; depression, $t(504) = 0.09$, *ns*; PTSD, $t(512) = 0.12$, *ns*; re-experiencing, $t(532) = 0.47$, *ns*; avoidance, $t(533) = 0.24$, *ns*; and hyper-arousal, $t(527) = 0.19$, *ns*.

Participants

Three hundred eighty-seven students with complete data for the variables were included in the data analysis: 176 (45.5%) were male, and 211 (54.5%) were female. The mean age of the students was 14.27 years (*SD* = 2.13). Age was further categorized into three age groupings that correspond to the different developmental tasks and competencies of middle childhood (9–11), early adolescence (12–14), and middle adolescence (15–18). Forty-four (11.4%) of the students were in the 9–11 age group (male = 17, female = 27), 165 (42.6%) were in the 12–14 age group (male = 77, female = 88), and 178 (46.0%) were in the 15–18 age group (male = 82, female = 96). Two hundred eighty-two (72.9%) of the students identified themselves as Caucasian, 47 (12.1%) identified as African American, 20 (5.2%) identified as Hispanic, 19 (4.9%) identified as mixed race, and 19 (4.9%) reported other or unknown ethnic affiliation.

Measures

The measure used for this study was the NCTSN Hurricane Assessment and Referral Tool for Children and Adolescents (NCTSN, 2005). The NCTSN assessment scale of posttraumatic symptoms was based on the validated UCLA PTSD Index and includes a number of questions regarding depressive symptoms. The measure consists of 22 items on a 4-point Likert scale, with 1 representing *not at all*, 2 representing *a little bit*, 3 representing *quite a bit*, and 4 representing *very much*. The measure was modified by the LSUHSC Department of Psychiatry in collaboration with school administrators and students to aid in the students' ability to complete the scale. In addition to modifications of the wording of the screener to make it easier for the students to fill out themselves, another modification included changing the original 5-point Likert scale to a 4-point Likert scale. To score the screener, 1 point is given for each question rated 3 or 4; four or more scores of 3 or higher suggest the need for referral for further evaluation and enhanced mental health services.

Symptomatology. Depression, overall PTSD, and PTSD subscales symptoms (re-experiencing, avoidance, and hyper-arousal) were derived from the NCTSN screener using clinical classification based on *DSM–IV–TR* criteria (American Psychiatric Association, 2000). The internal consistencies (α coefficient) for each scale and subscale were as follows: .91 for depression and .90 for overall PTSD. PTSD subscale alphas were .75 for re-experiencing, .60 for avoidance, and .81 for hyper-arousal. Depressive symptoms included: 6–9, 11–18, and 20; for example, nothing is fun anymore (Item 6), sleep difficulties (Item 7), feeling jumpy nervous (Item 8), difficulty concentrating (Item 9), feeling irritable (Item 11), feeling sad (Item 12), appetite change (Item 13), headaches or stomachaches (Item 14), less energy (Item 15), difficulty with schoolwork (Item 16), worry about something bad happening (Item 17), difficulty with family or friends (Item 18), and harder to enjoy activities (Item 20). PTSD symptoms included: upset when thinking about hurricane (1), nightmares (2), upsetting thoughts (3), try not to think or talk about hurricane (4), stay away of trauma reminders (5), sleep difficulties (7), feeling jumpy or nervous (8), difficulty concentrating (9), worry about what will happen (10), difficulty with schoolwork (16), and worry about something bad happening (17). PTSD subscale symptoms included items: 2, 3, and 10 for re-experiencing; 1, 4, and 5 for avoidance; and 7–9 and 16 for hyper-arousal. These scores represent symptoms based on a self-report measure and are not considered diagnoses of PTSD or depression.

Outcome trajectories. For person-centered analyses, students were classified according to recovery patterns adapted from Masten and Obradovic (2008). The trajectories included stress resistant, normal response and recovery, delayed breakdown, and breakdown without recovery. Classification was based on whether or not participants met the criteria for referral in the 2nd (2006–2007) and 3rd (2007–2008) post-Katrina school years. Students who did not meet the cutoff for referral on the screening measure in either year were classified as stress resistant. Students who met the cutoff on the screening measure in the second post-Hurricane Katrina year but did not meet the cutoff in the 3rd year were classified as normal response and recovery. Students who met the cutoff for both post-Hurricane Katrina years were classified as breakdown without recovery, and students who did not meet the cutoff in the 2nd post-Hurricane Katrina year, but met the cutoff in the 3rd year were classified as delayed breakdown.

Life stressors. Adversity scores included recovery stressors related to the aftermath of the hurricane, significant loss or trauma pre- and post-Hurricane Katrina, and current perceptions of life problems. Hurricane recovery stressors were assessed through student endorsement of the following variables: consultation with a mental health counselor or therapist since the storm, housing others due to storm, still living in a trailer, home needed renovation, currently residing in home under renovation, and parent still unemployed due to hurricane. Hurricane recovery stressors were also assessed by students' reports on a 1–10 scale of how connected they felt to their family, with 1 representing limited or no connectedness; total number of places they reported living since the storm, and the total number of schools they attended since the storm. Significant loss or trauma was operationalized as having experienced a major loss or trauma prior to or since Hurricane Katrina. The index of current problems was based on concerns reported in the 3rd-year assessment. Problems were operationalized as dichotomous variables on whether or not the student reported family, school, friend, financial, housing, or whether they reported problems with neighborhood violence. Descriptive statistics on life stressor variables by outcome trajectory are presented later in Table 3.

Results

Reported Symptoms of Depression and PTSD

Mixed method (two-between/one-within) analysis of variance (ANOVA) was used to assess

Note. Numbers in parentheses represent mean squared error. Depression = D, PTSD = P, re-experiencing = R, avoidance = A, and hyper-arousal = H. 2006–2007 > 2007–2008; for 2006–2007 and 2007–2008, 9–11 > 12–14 on D, P, R, and H, and 9–11 > 15–18 on D, P, R, and H; for 2007–2008, 9–11 > 15–18 on A. Females > males on D, P, R, and A. ANOVA = analysis of variance; PTSD = posttraumatic stress disorder.
$^*p < .05$.

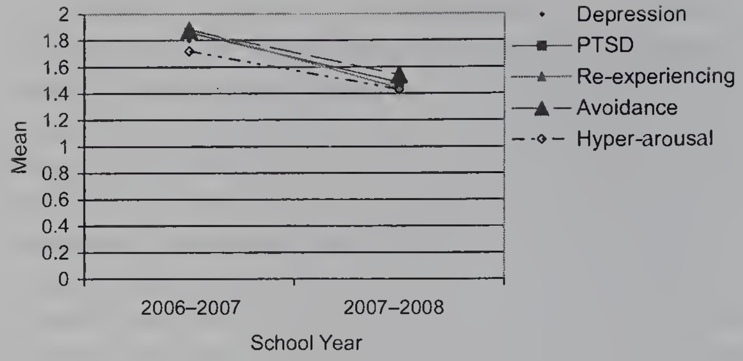

Figure 1. Line graph displaying symptom means by school year.

differences between the 2nd and 3rd post-Katrina years (2006–2007 vs. 2007–2008) on students' reported symptoms of depression and PTSD by age (9–11 vs. 12–14 vs. 15–18) and by gender (male vs. female). Table 1 presents the results, where within-subjects main effects were shown on depression, overall PTSD, and PTSD subscales (re-experiencing, avoidance, and hyper-arousal). Within-subjects main effects showed a statistically significant decrease on symptom scores (see Figure 1) between the 2nd and 3rd post-Katrina years (2006–2007 vs. 2007–2008). Between-subjects main effects were shown on depression, PTSD, re-experiencing, avoidance, and, hyper-arousal by age, and on depression, PTSD, re-experiencing, and avoidance by gender. No significant Age × Gender interaction effects were revealed. Table 2 presents the mean symptom scores by age and by gender. Interpretations of results using post hoc comparisons for the significant between subject main effects are presented next; for all post hoc comparisons alpha levels were set at $p < .01$.

Age. Fifteen post hoc tests were conducted to assess if differences exist from the 2nd to 3rd post-Katrina years on the symptoms (depression, PTSD, re-experiencing, avoidance, and hyper-arousal) for each age category. Results of the paired sample *t* tests revealed statistically significant decreases on symptoms from the 2nd to 3rd post-Katrina years for students in the: 9–11, $t(43) = 2.87–4.66$, *p*s < .01; 12–14, $t(164) = 4.80–9.03$, *p*s < .01; and 15–18, $t(177) = 4.72–7.81$, *p*s < .01, age categories. Ten one-way ANOVAs were also conducted to assess age differences on the 2006–2007 and the 2007–2008 symptoms measures (depression, PTSD, re-experiencing, avoidance, and hyper-arousal). Significant age differences were revealed on the 2006–2007 symptom measures of depression—PTSD, re-experiencing, and hyper-arousal, $F(2, 384) = 4.86–8.52$, *p*s < .01—and on the 2007–2008 symptom measures—depression, PTSD, re-experiencing, avoidance, and hyper-arousal, $F(2, 384) = 4.86–8.32$, *p*s < .01. Scheffe post hoc tests suggest that for both academic years (2006–2007 and 2007–2008), students in the 9–11 age category scored significantly higher on depression, PTSD, re-experiencing, and hyper-arousal compared with students in the 12–14 and 15–18 age categories. Tests also suggest

Table 2
Means Symptom Scores by Age and by Gender

		Ages 9–11			Ages 12–14			Ages 15–18			Total		
Symptom	Time	Male	Female	Total	Male	Female	Total	Male	Female	Total	Male	Female	Total
Depression	1	2.07	2.20	2.15	1.65	1.93	1.8	1.57	1.86	1.72	1.65	1.93	1.80
	2	1.74	1.87	1.82	1.33	1.52	1.43	1.31	1.56	1.45	1.36	1.58	1.48
PTSD	1	2.15	2.32	2.25	1.7	1.95	1.83	1.6	1.94	1.78	1.70	1.99	1.86
	2	1.61	1.95	1.82	1.33	1.57	1.46	1.28	1.55	1.42	1.33	1.61	1.48
Re-experiencing	1	2.16	2.46	2.34	1.71	2.01	1.87	1.64	1.93	1.80	1.72	2.03	1.89
	2	1.51	1.96	1.79	1.29	1.52	1.41	1.24	1.52	1.39	1.29	1.57	1.44
Avoidance	1	2.00	2.33	2.2	1.77	1.93	1.86	1.54	2.07	1.83	1.69	2.05	1.88
	2	1.53	1.96	1.8	1.43	1.67	1.56	1.28	1.60	1.45	1.37	1.68	1.54
Hyper-arousal	1	2.15	2.12	2.13	1.58	1.79	1.69	1.52	1.74	1.64	1.61	1.81	1.72
	2	1.74	1.81	1.78	1.28	1.48	1.38	1.28	1.47	1.38	1.32	1.52	1.43

Note. Time 1 = 2006–2007 school year; Time 2 = 2007–2008 school year. Depression = D, PTSD = P, re-experiencing = R, avoidance = A, and hyper-arousal = H. 2006–2007 > 2007–2008; 9–11 > 12–14 on D, P, R, A, and H, and 9–11 > 15–18 on D, P, R, and H. Females > males on D, P, R, and A. PTSD = posttraumatic stress disorder.

that for the 2007–2008 academic year, students in the 9–11 age category scored significantly higher on avoidance compared with students in the 15–18 age category. There were no significant differences on symptom measures between the 12–14 and the 15–18 age categories.

Gender. Eight post hoc tests were conducted to assess whether differences exist between the 2nd and 3rd post-Katrina years on the symptoms (depression, PTSD, re-experiencing, and avoidance) for each within-gender subgroup. Results of the paired sample t tests revealed statistically significant decreases on symptoms between the 2nd and 3rd post-Katrina years for both males, $t(175) = 5.58–8.57$, $ps < .001$, and females, $t(210) = 6.14–9.37$, $ps < .001$. Eight independent sample t tests were also conducted to assess gender differences on the 2006–2007 and the 2007–2008 symptom measures of depression, PTSD, re-experiencing, and avoidance. These post hoc tests further revealed that females scored significantly higher than males on the 2006–2007 measures of depression, PTSD, re-experiencing, and avoidance, $t(385) = 3.87–4.53$, $ps < .001$, and the 2007–2008 measures of depression, PTSD, re-experiencing, and avoidance, $t(385) = 3.83–4.57$, $ps < .001$.

Outcome Trajectories Following Trauma

Students who completed the screening measure during the 2nd and 3rd post-Katrina years were classified according to the outcome trajectories described by Masten and Obradovic (2008): 175 (45.2%) students were classified as stress resistant, 105 (27.1%) as normal response and recovery, 18 (4.7%) as delayed breakdown, and 89 (23.0%) as breakdown without recovery. Mean total screener scores for the 2007–2008 school year by outcome trajectory are as follows: 0.74 ($SD = 0.83$) stress resistant, 1.49 ($SD = 1.09$) normal response and recovery, 5.39 ($SD = 1.91$) delayed breakdown, and 8.27 ($SD = 4.09$) breakdown without recovery, demonstrating that posttraumatic stress symptoms increased by trajectory classification, from resistant and recovery to delayed and continued breakdown classifications. Descriptive statistics on life stressors, age, and gender by outcome trajectory are presented in Table 3.

The following analyses were conducted to assess the relation between outcome trajectories and life stressors. Given the limited number of students in the delayed breakdown classification, chi-square tests were conducted to assess whether differences existed between the delayed breakdown and breakdown without recovery trajectories by the life stressor variables. Results revealed no significant differences, which supported combining of the two categories. Therefore, for statistical purposes, the delayed breakdown category was collapsed into the breakdown without recovery category ($n = 108$).

Although St. Bernard Parish was a heavily devastated area, analyses were conducted to assess the level of exposure by outcome trajectory. Level of exposure was operationalized by six questions including, did the student: have to be separated from a caregiver (23.0%), witness injury (13.7%), experience personal injury (4.1%), have family or friends injured (18.6%), have family or friends

Table 3

Chi-Square Statistics on Trajectories by Age, Gender, and Life Stressors

Variables	Stress resistant (n = 174)	Normal response and recovery (n = 105)	Breakdown without recovery (n = 108)	χ^2
Age				
9–11	10 (22.7)	12 (27.3)	22 (50.0)	15.79**
12–14	76 (46.1)	50 (30.3)	39 (23.6)	
15–18	88 (49.4)	43 (24.2)	47 (26.4)	
Female	74 (42.5)	65 (61.9)	72 (66.7)	18.83**
Consulted with mental health counselor/therapist since storm	24 (13.8)	17 (16.2)	38 (35.2)	20.35**
Problems/worries				
Family	6 (3.4)	11 (10.5)	27 (25.0)	30.83**
School	23 (13.2)	23 (21.9)	52 (48.1)	43.88**
Friend	12 (6.9)	12 (11.4)	42 (38.9)	51.44**
Financial	10 (5.7)	10 (9.5)	22 (20.4)	14.99**
Housing	5 (2.9)	6 (5.7)	21 (19.4)	25.36**
Neighborhood violence	5 (2.9)	6 (5.7)	17 (15.7)	16.94**
Previous loss or trauma	35 (20.1)	28 (26.7)	42 (38.9)	11.89**
Post hurricane loss or trauma	37 (21.3)	33 (31.4)	47 (43.5)	15.74**
House others due to storm	12 (6.9)	8 (7.6)	19 (17.6)	9.37**
Still living in a trailer	23 (13.2)	18 (17.1)	26 (24.1)	5.49**
House fixed or needed renovation	130 (74.7)	79 (75.2)	75 (69.4)	1.20
Currently renovating house	38 (21.8)	26 (24.8)	32 (29.6)	2.17
Parent still unemployed	18 (10.3)	13 (12.4)	21 (19.4)	4.88

Note. Numbers in parentheses represent percentages.
**$p < .01$.

killed (12.7%), and have personal belongings destroyed (94.8%). Questions were summed together to obtain a total level of exposure score; the minimum score was 0 and the maximum score was 5 (M = 1.67, SD = 0.84). An ANOVA was conducted, $F(2, 384) = 9.49$, $p < .001$, and revealed that differences existed among the outcome trajectories and level of exposure. Scheffe post hoc tests were conducted and revealed that students in the stress-resistant trajectory had lower levels of exposure (M = 1.47, SD = 0.84) compared with students in the normal response and recovery (M = 1.72, SD = 0.89) and breakdown without recovery (M = 1.94, SD = 1.03) trajectories.

Bivariate Analyses

Chi-square tests were conducted to assess relation between outcome trajectories (stress resistant, normal response and recovery, and breakdown without recovery) and age categories, gender, and life stressors. Results and descriptive statistics are presented in Table 3. Post hoc examination was also conducted to assess individual differences. Results revealed significant age differences, suggesting that a greater proportion of students in the breakdown without recovery group were in the 9–11 age category and lower proportions were in the 12–14 age category compared with the stress-resistant and normal response and recovery trajectories. Results on age differences also revealed that a greater proportion of students in the breakdown without recovery group were in the 9–11 age category and lower proportions were in the 15–18 age category compared with the stress resistant trajectory. Results on gender differences were significant indicating that a greater proportion of females were classified in the breakdown without recovery and normal response and recovery group compared with the stress-resistant group.

Results indicate that greater proportions of students in the breakdown without recovery classification reported consulting with a mental health counselor or therapist; endorsing family, school, friend, financial, housing, or neighborhood violence problems or worries; experiencing previous loss or trauma; posthurricane major loss or trauma; housing others due to the storm; and still living in a trailer when compared to students with stress-resistant and normal response and recovery classifications. The results further indicate that greater proportions of students in the normal response and recovery group endorsed school or friend problems and experienced previous loss or trauma or posthurricane loss or trauma, compared with the stress-resistant group. There were no significant differences among outcome trajectories and house-needed renovation, currently residing in house under renovation, and parent still unemployed due to hurricane.

One-way ANOVAs were conducted to assess if differences existed on family connectedness, number of places lived since the storm, and number of schools attended since the storm by outcome trajectory (stress resistant, normal response and recovery, and breakdown without recovery). Results and descriptive statistics are presented in Table 4. Scheffe post hoc tests revealed that students in the breakdown without recovery group reported lower family connectedness, compared with students in the stress-resistant and normal response and recovery groups. Results also indicate that students in the breakdown without recovery group reported living in more places since the storm, compared with students in the stress-resistant group. There were no significant differences in outcome trajectory by number of schools attended since the storm.

Multinomial Logistic Regression

A multinomial logistic regression was conducted to assess the additive effect of age, gender, and the life stressor variables on classification of the outcome trajectories (stress resistant vs. normal response and recovery vs. breakdown without recovery). The following life stressor variables were included in the regression due to significant bivariate relation with the outcome trajectories: consultation with a mental health counselor or therapist since the storm; endorsement of family, school, friend, financial, housing, or neighborhood violence problems; prehurricane losses or trauma; posthurricane losses or trauma; housing others due to storm; still living in a trailer; family connectedness; and number of places lived since the storm. Breakdown without recovery was the reference category and the enter method was used. All variance inflation factors were under 2 suggesting the absence of multicollinearity; all other assumptions were met.

There was a good model fit (discrimination among groups) on the basis of the constant only model (no predictors were entered and assessed if classification was based on chance alone) $\chi^2(640.80)$, $p = .72$. After adding the life stressor variables, the test of the overall model, likelihood ratio, was significant, $\chi^2(32) = 143.32$, $p < .001$, Nagelkerke = .351. The life stressor variables collectively classified 62.8% of the students as stress resistant, 12.4% as normal response and recovery, and 24.8% as the breakdown without recovery with an overall correct classification of 57.9%.

Table 5 shows the contribution of the individual predictors to the overall model by comparing models with and without each predictor. Age significantly enhanced prediction, with students ages 15–18 compared to younger students (ages 9–11) being 4.11 times more likely to be in the stress-resistant trajectory than the breakdown without recovery trajectory. Gender also significantly enhanced prediction, with female students being almost twice as likely (OR = 1.97, $p < .05$) to be classified as breakdown without recovery compared with stress resistant. Three of the life stressor variables significantly enhanced prediction. The

*$p < .05$.

greatest effect in classification of the outcome trajectories was contributed by the following variables: needed to consult with a mental health professional due to stress since the storm and endorsement of family and school problems. The following paragraph presents the interpretation of the odds ratios for the significant individual predictors.

Students who needed to consult with a mental health professional had 2.30 greater odds ($p < .05$) of being classified as breakdown without recovery compared with stress resistant and 2.31 greater odds ($p < .05$) of being classified as breakdown without recovery compared with normal response and recovery. Students who endorsed family (OR = 4.33, $p < .001$) or school (OR = 3.25, $p < .001$) problems were over 3 times more likely to be in the breakdown without recovery trajectory than the stress-resistant trajectory. Students who endorsed family (OR = 2.80, $p < .05$) or school (OR = 2.01, $p < .05$) problems were twice as likely to be in the breakdown without recovery trajectory compared to normal response and recovery.

Moderation analyses were also conducted to assess whether interactions existed among age, gender, and the three variables with significant odds ratios in the regression model (needing to consult with a mental health professional since the storm, and endorsing family and school problems). All variables were centered prior to analysis and mean age was used. Results showed that the interactions of age with mental health consultation and endorsing family or school problems were not significant. Results also showed that the interactions of gender with mental health consultation and endorsing family or school problems were not significant. The lack of moderation suggests that age and gender do not alter the relation between mental health consultation and endorsing family or school problems with the outcome trajectory classifications.

Summary

The first hypothesis, that student reports of PTSD and depressive symptoms would decrease over time and changes in symptoms would be related to age and gender, was supported. Results showed a statistically significant decrease in depression, overall PTSD, and PTSD subscales (re-experiencing, avoidance, and hyper-arousal) scores between the 2nd and 3rd post-Katrina years (2006–2007 vs. 2007–2008). Results also revealed that younger students (ages 9–11) scored significantly higher on depression, PTSD, re-experiencing, avoidance, and hyper-arousal compared with older students (ages 12–18). Results also showed that females scored significantly higher on depression, PTSD, re-experiencing, and avoidance than males.

The second hypothesis, that adversity and perceived life stressors would classify students' recovery patterns into one of four outcome trajectories (stress resistant, normal response and recovery, breakdown without recovery), was also supported. The greatest influence in classification of the outcome trajectories was contributed by the following variables: age, gender, consultation with a mental health professional since the storm, and endorsement of family or school problems. Although bivariate relation existed between outcome trajectories and endorsement of friend, financial, housing, or neighborhood violence problems; prehurricane losses or trauma; posthurricane losses or trauma; housing others due to storm; still living in a trailer; and number of places lived since the storm, they did not contribute to the overall regression model. The life stressor variables, home needed renovation, currently residing in home under renovation, parent still unemployed due to hurricane, and number of schools attended since the storm, were not related to the outcome trajectories.

The third hypothesis, that age and gender would moderate the relation between the life stressor variables and outcome trajectories, was not supported. Results suggest that age and gender do not alter the relation between mental health consultation and endorsing family or school problems with the outcome trajectory classifications.

Discussion

The purpose of this study was to examine not only the symptomatology endorsed by children who lived in an area heavily devastated by the major disaster, Hurricane Katrina, but also to learn more about the recovery patterns of these children and life stressors that influence these patterns. This study focused on the developmental factors of age, gender, and life stressors associated with multiple developmental systems and their impact on the course of children's recovery patterns. In order to track recovery, stressors and resultant symptoms in these youth were studied for 3 years following the hurricane.

Major disasters with slow recovery can result in acute and chronic psychological effects, which can impact development by interrupting normal developmental trajectories (Pynoos et al., 1999). Compas et al. (1995) describe the multiple influences on development including internal processes and external environmental factors, which lead to various adaptive and maladaptive trajectories of development. They assert that, in general, adolescents who live in environments that are relatively free of significant stressors will demonstrate ongoing and stable adaptive functioning characterized by a positive sense of self and a lack of severely problematic behaviors or significant emotional problems. The overall adaptive pathway may veer toward dysfunction when trauma is a precursor to clinical depression and PTSD, which cause significant distress in social, occupational, or other important areas of functioning (American Psychiatric Association, 2000). As adolescent functioning is associated with adult functioning (Compas et al., 1995), trauma in childhood and adolescence may have a long-lasting impact. Due to the long-term life stressors associated with Hurricane Katrina as well as individual and environmental supports, children and adolescents have exhibited complex reactions and have demonstrated trauma responses ranging from stress resistance and recovery to continued breakdown. The results of this study provide insight into factors that contribute to different outcomes.

One of the most important outcomes of this study relates to the strengths shown by students in St. Bernard Parish. Not only did overall symptoms decrease from the 2nd to 3rd post-Katrina years, but also 45.2% of the children and adolescents were classified as stress resistant and did not report high levels of symptomatology when assessed 2 and 3 years following the disaster. These data are consistent with the findings of Bonanno and Mancini (2008) who estimated that about half of all children and adolescents will display no immediate or long-term psychological sequelae following traumas including bereavement, terrorism, and health-related traumas. Further, 27.1% of the children and adolescents were classified as normal response and recovery, which means that they reported symptoms of PTSD and depression during the 1st year following the hurricane, but few symptoms during the 2nd year. The finding that 72.3% of the children were classified as stress resistant or experienced normal response and recovery, although consistent with other literature on disasters (La Greca et al., 1996), is striking given the extent of the devastation, slow recovery, and conditions under which participants lived in St. Bernard Parish following Hurricane Katrina. Perhaps these are the children described as ''resilient'' in the current literature.

Resilience has been a topic of great interest to researchers as a way to potentially explain why some children succeed despite adversity. Although researchers have posited numerous definitions of resilient patterns of recovery including ''succeeding in spite of serious challenges to their development'' (O'Daugherty & Masten, 2005, p. 17), ''early effective efforts at adjustment and recovery'' (Pynoos et al., 1999, p. 1542), ''facing adversity and nonetheless do(ing) well'' (Sroufe, 1997, p. 256), and ''the ability to maintain healthy levels of psychological and physical functioning as well as the capacity for generative experiences and positive emotions'' (Bonanno & Mancini, 2008, p. 371), they generally agree that adaptive patterns of functioning in children following a trauma are common (Bonanno & Mancini, 2008; Masten, 2001). Sroufe, Egeland, Carlson, and Collins (2005) expand the understanding of resilience by describing the concept ''not as an individual trait but a feature of the developmental system'' (p. 227) that is associated with a foundation of early support and attachment. Positive recovery patterns are associated with self-efficacy, positive coping and problem-solving skills, self-regulation, and supportive social systems including family, peer group, and school (Masten & Obradovic, 2008).

Although our findings, in general, suggest a high level of resilience among children, it is also important to note that during the 3rd year after Hurricane Katrina, 27.7% experienced breakdown without recovery or delayed breakdown. In other words, although the majority of the sample showed positive signs of recovery with symptoms decreasing over time, more than one fourth of children reported significant symptoms of posttraumatic stress and depression and met the cutoff to qualify for mental health referral 3 years after the hurricane. These students also reportedly had higher levels of exposure, which may affect their resilience. The elevated levels of long-term symptomatology were not unexpected given the slowness of recovery and conditions of the community; however, this finding is important in understanding recovery in order to learn more about why some children showed very few symptoms and others remained symptomatic over time.

Based on the results of this study, several factors were associated with recovery patterns. Specifically, younger students, females, individuals who consulted with a mental health professional since the storm, experienced previous loss or trauma, experienced posthurricane major loss or trauma, housed others due to the storm, continued to live in a trailer, had limited family connectedness, lived in a greater number of places since the storm, and endorsed financial, housing, family, school, friend, or neighborhood violence problems were more likely to have continued negative responses to the hurricane. The most influential of these developmental and systemic factors related to students' responses were age, gender, consulting with a mental health professional, and endorsing family and school problems. These issues will be elaborated as follows.

In terms of age differences, in general, children who are younger may be more vulnerable as they have not had the opportunity to develop their own coping capacity when compared with older children, and they likely depend much more on adults in their environment for support (Osofsky, 2004). The results of this study were consistent with the idea of increased vulnerability for younger children and revealed that younger students (ages 9–11) scored significantly higher on depression, PTSD, re-experiencing, avoidance, and hyper-arousal compared with older students (aged 12–18). Further, students in the breakdown without recovery category when compared with those in the stress resistant group were significantly younger. These younger children may be less likely to be able to access systems of support to cope with the continuing disruption in their homes and neighborhoods. A study by Cryder, Kilmer, Tedeschi, and Calhoun (2006) supports this outcome as they found that among 6- to 15-year-old children, older children, when compared with younger children, were more likely to have social support systems that included friends and adults outside of their immediate family. Social support was associated with positive outcomes including posttraumatic growth approximately 1 year following Hurricane Floyd. Thus, younger children's limited social support may be considered a risk factor to positive postdisaster recovery. This issue of increased vulnerability for younger children highlights the importance of developing strategies to support the developmental needs of children exposed to trauma, a consideration that is rarely addressed in overall planning for disaster response (Osofsky et al., 2007).

As might be expected and consistent with much of the available literature related to gender effects on mental health (Bal, 2008; Giannopoulou et al., 2006; John et al., 2007; Pfefferbaum, 1997; Shannon et al., 1994), females reported more symptoms of depression than males. A greater proportion of females were classified in the breakdown without recovery and normal response and recovery group when compared with males for whom a greater proportion were in the stress-resistant group. Overall, it appears that the male patterns of functioning over the 2nd and 3rd years following the disaster were more likely to indicate positive patterns of recovery, whereas some females showed recovery to good adaptive functioning and others displayed more maladaptive patterns. These results may be related both to the increased vulnerability of females to depressive symptoms and differences in the availability of support networks that are often so important for recovery. An alternative interpretation for this finding that boys are more likely to be stress resistant than girls is that boys are more likely to underreport symptoms of posttraumatic stress and depression. This is supported by research that has shown that girls and boys respond with different symptomatology following trauma. It is possible that boys respond to trauma with increased behavioral, attention, and academic problems, whereas girls may be more likely to respond to trauma with increased guilt and emotional reactions (Kar & Bastia, 2006; Shannon et al., 1994).

As would be expected, children and adolescents who experienced breakdown without recovery were more likely to have consulted a mental health professional related to stress following the hurricane and to report school and family problems. This finding may be interpreted as a positive indicator that school and community mental health services are available and accessible to children who exhibit long-term symptomatology and need mental health intervention. This may also contribute to the strength of children in this classification in that their families and schools recognize their need for and seek out mental health treatment. The issue of utilization of mental health services highlights the importance of having such supports and services easily accessible, especially in school settings in the postdisaster environment.

Students with concerns about their families were more likely to continue to show symptoms 3 years after the hurricane. This finding highlights the importance of supporting parents and the caregiver–child relationship after disasters and is consistent with the resilience literature (Masten, 2001). The current study focuses on stressors faced by children following Hurricane Katrina; however, their parents also experienced significant distress following the storm (Kessler et al., 2006). They faced multiple losses including loss of homes and jobs and loss of or separation from family members and friends. An important lesson learned from these data is that in planning disaster responses, it is crucial for the well-being of children to be mindful of the psychological needs of their parents and to provide as much ongoing support as possible for families as communities work to rebuild.

Results of this study also revealed that children's worries about school were significantly associated with long-term distress. This is consistent with literature on multisystemic pathways associated with trauma recovery (Compas et al., 1995; Sroufe et al., 2005). A recent study related to Hurricane Katrina stress provides support for the relation between school problems and recovery. When eighth-grade students with both test anxiety and PTSD symptoms participated in an intervention that addressed test anxiety, both test anxiety and PTSD symptoms decreased (Weems et al., 2007). Given that multiple systems (e.g., family and school) are affected by trauma, treatment that includes family members and addresses family, school, and peer issues as well as the actual traumatic event may be the most effective intervention and treatment.

Limitations

One of the limitations of the current study, and disaster studies in general, is the lack of predisaster baseline data. Although mental health symptoms were elevated with different outcome trajectories related to the stressors, it is not clear what the premorbid levels of symptoms and functioning were for children and adolescents in the disaster area. Another inherent flaw with longitudinal studies of disaster outcomes is the possibility of incomplete history; that is, some other phenomenon may have caused the symptoms or patterns. Although the lack of statistical significance for pre- and posthurricane losses or traumas in the overall regression model aids in addressing this issue, other factors not measured in this study may affect the outcomes.

Another limitation to this study is generalizability related both to the location of the sample in a relatively small, homogeneous parish with multigenerational family involvement and the severity of the devastation. Without the extent of the devastation, slow recovery, and family and community disruptions in support, it is possible that characteristics of recovery response would be somewhat different. This study also does not account for, and the findings cannot be generalized to, those individuals who did not return or returned but did not remain in the parish. This group is an important population for future research. Also given that fewer students were in the 9–11 age grouping, it may be that families with younger children did not return as rapidly. This may not only be a limitation to the sample but may also account for the lack of interaction between age and gender.

A final limitation is related to the measurement of exposure variables and psychological status. The measurement tool utilized in this survey was the NCTSN Hurricane Assessment and Referral Tool for Children and Adolescents (NCTSN, 2005), a measure based on the validated UCLA PTSD Index that also includes a number of questions regarding depressive symptoms. The overall measure has not been standardized, and although it is theoretically and clinically informed, no psychometric data are available for symptom and cutoff scores. This assessment tool is currently being evaluated.

Future Research

Research on the short- and long-term effects of disasters on children and adolescents, including data from this study related to disaster impact 2–3 years post-Hurricane Katrina, lead to a strong recommendation for additional research related to the psychological effects of disasters on children. Such research needs to include studies of children of different ages, outcome trajectories, and developmental progression. It is also important to continue following the children of Katrina in order to assess longer-term effects and assessments to learn more about students who move from positive to negative postdisaster responses. Such research will advance the science of disaster research and also provide crucial information about ways to better prepare for future disasters and the aftermath. Given the availability of the current data, future research studies will be able to include pre–post data that can then be used to develop meaningful postdisaster interventions and influence policy related to disaster response. This information will also provide more understanding of the effects of different types of disasters, specific response and recovery patterns that can be expected, and the impact on developmental trajectories. The results found in this study provide a step toward looking at the full array of recovery patterns.

This study also highlights the need for more research on factors contributing to resilience. Particular to this study, students who were older, male, did not actively seek mental health treatment, or endorse family and school problems tended to show patterns of positive recovery associated with resilience. Further, students who suffered significant losses following Hurricane Katrina and who had higher levels of storm-related exposure (i.e., injury to self, family, or friends) were more likely to be in the breakdown without recovery or the normal response and recovery group compared with children and adolescents in the stress-resistant group. Future research should address other factors contributing to resilience such as self-efficacy, positive supports, and better coping skills along with exposure to disasters or trauma as it relates to patterns of recovery.

Another promising area of research relates to the evaluation of the effectiveness of developmentally grounded predisaster preparedness on outcomes for children and families (Osofsky et al., 2007). In this parish that was heavily impacted by Hurricane Katrina, patterns of recovery were assessed on several levels. More data are needed in intersecting areas including predisaster functioning, environmental risk, previous exposure to trauma and loss, family disruption, and financial difficulties and their impact on the experience of evacuation, displacement, and subsequent resilience and recovery trajectories. However, considerable information is already available based on findings from this and other studies that will facilitate future planning and preparation in ‘‘disaster-prone’’ areas and developmentally informed responses in preparing for and responding to disasters.

Lessons Learned

It is evident in St. Bernard Parish that the school environment provides a community for children where they not only learn academic skills but also develop social relationships with peers and teachers. For the participants in this study, the positive features of their school environment likely contributed to the resilience and recovery of children despite the ongoing struggles. In spite of the devastation, St. Bernard Parish Unified Schools reopened within 2½ months following Hurricane Katrina with a commitment to being a significant source of support for children and families following the devastation of their community. In disaster planning for children, it is crucial not only to support parents and caregivers but also to focus on building support through schools and community activities. When children returned to school, they were surrounded by peers who had experienced similar trauma; many of those children, particularly those who showed resilience, were likely able to maintain and build their peer groups in this setting following the disaster.

Placing more focus on resilience and recovery in addition to risk and risk mitigation will significantly benefit future research and disaster planning. Given the extent of the devastation and the complexity of recovery resulting from Hurricane Katrina and similar large-scale disasters, we have the opportunity to learn more about these patterns of recovery as well as continuing symptomatology in children, adolescents, and families. Such information will be helpful in planning ways to provide support and enhance development during the recovery period as communities rebuild. Building on these ideas, in a collaborative meeting with the schools, one of the authors of the current study (B. Lawrason, February 2008) noted, "It is not whether our children will recover. It is how they recover, what scarring remains, and how we can help them achieve their potential."

Children With Disabilities in the Context of Disaster: A Social Vulnerability Perspective

Lori Peek
Colorado State University

Laura M. Stough
Texas A&M University

An estimated 200 million children worldwide experience various forms of disability. This critical review extrapolates from existing literature in 2 distinct areas of scholarship: one on individuals with disabilities in disaster, and the other on children in disaster. The extant literature suggests that various factors may contribute to the physical, psychological, and educational vulnerability of children with disabilities in disaster, including higher poverty rates, elevated risk exposure, greater vulnerability to traumatic loss or separation from caregivers, more strain on parents, and poor postdisaster outcomes, unless medical, familial, social, and educational protections are in place and vital social networks are quickly reestablished. Future research needs are outlined in the conclusion.

Research on children and disaster has increasingly examined how certain characteristics, such as age and developmental levels, gender, and ethnicity, intersect and affect children's experiences in disaster (La Greca, Silverman, Vernberg, & Roberts, 2002; Peek, 2008). However, researchers have rarely considered how disability may contribute to the short- and long-term impacts of disaster on children. This represents a significant gap in knowledge, given that in the United States almost 9.2% of the school-aged population receives special education services (U.S. Department of Education, 2009), and an even higher percentage of children with disabilities are estimated to live in developing countries (World Health Organization [WHO], 2005).

In this review of the existing literature, we examine the special situation of children with disabilities in the context of disaster, highlighting research on the potential vulnerabilities, risks, and resiliency factors of this population with the goal of building a better knowledge base for future research in this area. We begin with an overview of the social vulnerability perspective and then summarize definitions of disability that are often used by scholars and practitioners working on disability issues in disaster. The subsequent sections of the article draw on empirical studies from disaster researchers and focus on the adverse physical, psychological, and educational vulnerabilities that children with disabilities may experience in the context of disaster. We conclude with a discussion of the theory of resilience as it pertains to children with disabilities in disaster and outline additional research needs.

Social Vulnerability and Disaster

Historically, disasters have been viewed as random events that cause indiscriminate losses and suffering among affected populations. However, in the mid-1970s, social scientists who pioneered the social vulnerability perspective began to question the ''naturalness'' of ''natural disasters'' (O'Keefe, Westgate, & Wisner, 1976). Proponents of the social vulnerability school assert that disasters are in fact a complex mix of natural hazards and human action (Cutter, Boruff, & Shirley, 2003; Wisner, Blaikie, Cannon, & Davis, 2004). Disasters are thus conceptualized as the product of the convergence of social, political, and economic factors that shape people's exposure to risk and ability to prepare for,

respond to, and recover from extreme events (Wisner et al., 2004, p. 4). This theoretical frame posits that we as a human society, rather than nature alone, decide who is more likely to live near or in the path of dangerous agents and to have weakened or no defenses against them (Hewitt, 1997, p. 141).

Disaster risk is socially distributed in ways that reflect preexisting inequalities, in that some groups are more prone to death, injury, economic loss, and psychological impairment in the wake of differing hazards (Wisner et al., 2004). Specifically, children, the elderly, women, racial minorities, the poor, persons with physical or mental disabilities, and immigrants have been identified by both disaster researchers and policy makers as especially vulnerable to the harmful impacts of disaster (Cutter et al., 2003). Although these groups differ in many ways, when viewed through a social vulnerability perspective they all can be seen as lacking access to vital economic and social resources, possessing limited autonomy and power, and having low levels of social capital (Morrow, 1999). They also, for sociohistorical and economic reasons, tend to live in the most hazardous regions and in the lowest quality housing, further exposing them to risks associated with natural hazards (Cutter et al., 2003; Wisner et al., 2004). Due to the disproportionate losses members of these marginalized groups suffer in disaster, they consequently have the hardest time recovering, creating vicious cycles of loss and vulnerability (United Nations Human Settlements Programme, 2007).

The social vulnerability paradigm, and the ensuing identification of vulnerable groups, has helped focus attention on those most at risk during and in the aftermath of disaster. Yet, social science research on vulnerable populations in disaster has tended to concentrate on single demographic factors—such as age, race, gender, or socioeconomic status—instead of examining the complex intersections between these categories (Phillips & Morrow, 2007). For example, it is clear that not all children are equally vulnerable to the impacts of disaster. Instead, the age of the child intersects with other personal and social characteristics, such as his or her geographic location, family structure, socioeconomic status, physical and mental ability, stage of development, and nationality, to determine the likelihood of harm in a particular disaster event. Given that these vulnerability factors tend to "cluster," certain segments of the population, such as children with disabilities, may experience amplified risk in disaster.

Defining Disability

Disability is a broad term that is not consistently defined. Its use varies according to societal norms and by the organizations, medical entities, and governmental agencies that address disability issues. The limited extant research on the effects of disaster on individuals with disabilities similarly has defined disability in a variety of ways. Mental health researchers typically use criteria from the American Psychiatric Association's (2000) *Diagnostic and Statistical Manual* to define samples with cognitive and psychological disabilities. Disaster researchers who study individuals with mobility impairments tend to use the Americans With Disabilities Act (1990) definition of disability as being "a physical or mental impairment that substantially limits one or more of the major life activities of such individual" (PL 101-336, 104 Stat. 327). Given their focus on disaster population statistics, epidemiologists often rely on the U.S. Census Bureau definition of disabilities, which allows for the analysis of data on persons with sensory, physical, mental, self-care, mobility, and employment-related disabilities. The emergency management field categorizes people who use wheelchairs, non-English speakers, and the elderly together as "special needs" populations.

Considering these varying taxonomies, definitions of disability in disaster research are best subsumed under the WHO's International Classification of Functioning, Disability, and Health (WHO, 2001). The ICF conceptualizes disability as resulting from the interaction between the health condition of an individual and that individual's personal and environmental setting. Thus defined, disability refers to an impairment in body functions or structures, a limitation in a specific activity, or a restriction in social participation. To date, research on the effects of disaster on people with disabilities has almost exclusively focused on how physical or cognitive impairments intersect with disaster experiences rather than on the interplay of disability with social and environmental factors. Kailes and Enders (2007) have proposed a functional-needs approach to defining disability in disaster, which highlights the supports individuals may need in the areas of communication, medical health, functional independence, supervision, and transportation. This functional-needs approach to disability was adopted by the U.S. Federal Emergency Management Agency and Department of Homeland Security Office for Civil Rights and Civil Liberties (2008) as part of its Comprehensive Preparedness

Guide 301 (CPG-301), which is designed to aid tribal, territorial, state, and local governments in planning for individuals with special needs during an emergency. The functional-needs approach has not yet been used, however, as a theoretical approach in disaster research on individuals with disabilities.

Identifying the precise number of individuals with disabilities within a particular sociocultural context also depends on the definition chosen. According to the WHO (2005), roughly 600 million people—10% of the global population—have some type of disability. Disability is highly correlated with poverty, and as many as 80% of all individuals with disabilities live in developing countries. The U.S. Census Bureau estimates the prevalence of disability in children between the ages of 6 and 15 to be nearly 13% (U.S. Census Bureau, 2005). The proportion of children with disabilities in developing countries is likely significantly higher, and it is estimated that over 200 million children worldwide have some type of disability (United Nations International Children's Emergency Fund, 2007).

Children, Disability, and Disaster

By the end of the 20th century, disasters affected an estimated 67 million children around the world each year (Penrose & Takaki, 2006). This number is projected to more than triple over coming decades, mostly due to population growth, especially in hazardous regions such as low-lying coastal zones, and the growing prevalence and severity of climate change-related disasters (Bartlett, 2008). Conservative estimates suggest that over 7 million of these disaster-affected children experience various forms of disability (United Nations International Children's Emergency Fund, 2007), and millions more may acquire disabilities as a result of increasingly frequent and intense disaster activity, wars, and landmine explosions (World Health Organization, 2005).

Scholarship on social vulnerability and disaster often lists both children and individuals with disabilities as populations at particular risk when disaster strikes. Consequently, two parallel tracks of research—one on children, the other on people with disabilities—have emerged within the disaster literature. Although an increasing amount of scholarly and applied attention has focused on the implications of disaster for children and youth, little empirical work has examined the effects of disaster on individuals with disabilities. The research that is available has focused on adult populations (Stough, 2009) and seldom mentions the needs of children with disabilities.

Given the dearth of research that reports on children with disabilities in disaster, we extrapolate from work in both areas to examine the potential implications of disasters for children with disabilities. To frame our discussion of the vulnerability and risk factors for children with disabilities, we draw on Peek's (2008) model that has previously been used to review research on children in disasters in terms of their physical, psychological, and educational vulnerabilities.

Physical Vulnerability

When disaster strikes, children are among those most vulnerable to death and injury, especially in developing countries (Neumayer & Plümper, 2007). Similarly, adults with disabilities or mobility impairments are at increased risk for mortality (Aldrich & Benson, 2008). Children and individuals with disabilities share a number of common risk factors that increase the probability that they will experience negative physical impacts during and following disaster.

First, children and people with disabilities are more likely to live in poverty both in developed and developing nations. In the United States, a higher percentage of children (18.3%) and individuals with severe disabilities (26%) live in poverty than the population as a whole (13.3%; U.S. Census Bureau, 2006). In most high-income countries, people under 18 years of age make up about 20% of the population; in low-income countries, where children are more likely to experience disability, children represent closer to half of the total population (e.g., 42% in Bangladesh, 51% in Nigeria, 57% in Uganda; Bartlett, 2008, p. 75). Poor people around the world are more physically vulnerable to natural disasters because they cannot afford to engage in prescribed preparedness actions, often do not receive or understand warning messages, are less likely to have the resources to evacuate a threatened area, and typically live in low-cost, lower-quality housing that is more prone to damage or collapse (Fothergill & Peek, 2004; Wisner et al., 2004). Children with disabilities in high-poverty areas are thus among those most exposed and most vulnerable to extreme events.

Second, in the case of sudden onset disasters that allow little warning time, such as tornados or earthquakes, children with disabilities may have a more difficult time taking recommended protective actions, escaping, or withstanding the force of the disaster. For instance, children with mobility limitations may be incapable of crouching under their desks in an earthquake, hiking up a hillside in a flash flood, or running to an evacuation point on higher ground in the event of a tsunami. All of these are recommended protective actions developed for people without mobility limitations. Children with cognitive impairments may not recognize signs of environmental danger or understand impending threats (Kailes & Enders, 2007) or may become anxious and confused in response to emergency signals (Scotti et al., 2007).

Third, even when evacuation is possible due to longer warning periods, such as with hurricanes, children with disabilities may be less likely to leave the threatened area thus putting them at increased risk for death or injury. Although much prior disaster research has shown that adults with children are *more likely* to respond to disaster warnings and evacuation orders than people without children, research on adults with disabilities has revealed that they are among those *least likely* to evacuate (see Dash & Gladwin, 2007). For example, studies on adults with sensory disabilities such as blindness or deafness suggest that these individuals often do not receive timely warning messages (Phillips & Morrow, 2007) and that they encounter significant barriers during evacuation (White, 2006). Van Willigen, Edwards, Edwards, and Hessee (2002) contrasted the experiences of households that had a family member with a disability with other households in North Carolina in the aftermath of Hurricanes Bonnie, Dennis, and Floyd. They found that evacuation rates were anywhere from 9% to 25% lower among those households that had a member of the family with a disability. These households were more likely to report that transportation issues and the lack of accessible shelters contributed to their decision not to evacuate. Research has also revealed that people with disabilities are less apt to have evacuation plans than those without disabilities (Spence, Lachlan, Burke, & Seeger, 2007).

Fourth, both children and people with disabilities are often excluded from emergency preparedness planning at all levels of government, leaving children with disabilities especially unprepared for emergencies. Disaster response professionals commonly assume that parents will inform, warn, and protect children in the event of disaster, even though children are frequently apart from their parents when in school, daycare, or with their friends (Mitchell, Haynes, Hall, Choong, & Oven, 2008; Phillips & Morrow, 2007). Likewise, emergency management agencies regularly do not include the needs of individuals with disabilities in their emergency preparedness policies, citing factors such as inadequate personnel or their own limited knowledge of disability (Fox, White, Rooney, & Rowland, 2007; Rowland, White, Fox, & Rooney, 2007). This lack of attention to disability-related needs in emergency management could result in children with disabilities being left behind in an evacuation or forced to evacuate without vital supports (e.g., mobility devices, respirators, medications, companion animals, etc.; Osofsky, Osofsky, & Harris, 2007; Rooney & White, 2007). As a case in point, approximately 100,000 children and their families evacuated from the city of New Orleans as a result of Hurricane Katrina (Casserly, 2006). Over one third of the children who remained displaced months after the storm had at least one diagnosed chronic medical condition, and their access to health insurance, continuous medical care, prescription medication, and specialized medical equipment was significantly compromised (Abramson & Garfield, 2006; Abramson, Redlener, Stehling-Ariza, & Fuller, 2007).

Fifth, children with disabilities may be in danger of suffering life-threatening consequences in the aftermath of disaster due to separation from parents and other caregivers. Children who are separated from their parents after disaster are more prone to illness and disease, malnutrition, and abuse, and may have difficulty in situations with prolonged deprivation associated with more chronic events such as droughts (Babugura, 2008; Bartlett, 2008). Individuals with physical disabilities, which include those with paralysis or who are medically fragile, are similarly susceptible to secondary illnesses in conditions in which their ongoing health needs are not appropriately addressed (Kinne, Patrick, & Doyle, 2004).

Sixth, the stigma, social distancing, and institutional exclusion often experienced by individuals with disabilities can further threaten the physical health and well-being of children with disabilities in the aftermath of disaster (Hemingway & Priestly, 2006; Tierney, Petak, & Hahn, 1988). For example, children with disabilities may acquire additional impairments and experience health issues as a result of inadequately staffed shelters that are not prepared to meet their medical needs. Indeed, the National Organization on Disability (2005) reports that shelters often do not offer equitable access to services for people with disabilities, which may also mean this group is overlooked in the distribution of basic relief and excluded from full participation in response and recovery activities (Hemingway & Priestly, 2006). In some developing countries, individuals with disabilities are socially stigmatized and face considerable social discrimination (Institute of Medicine, 2001), and anecdotal accounts suggest that some individuals with disabilities may even be purposely abandoned during disaster. For instance, news media reported that people with physical and cognitive disabilities were left behind during evacuation in the 2000 floods in Mozambique and Zimbabwe (United Nations Human Settlements Programme, 2007).

Psychological Vulnerability

Most of the research that has been conducted on children and disasters has explored their psychological vulnerability in the short-term aftermath of disaster (La Greca et al., 2002; Weissbecker, Sephton, Martin, & Simpson, 2008). This body of work collectively indicates that school-aged children are often more psychologically affected by disaster than adults and that children of different ages express trauma differently. Following direct exposure to disaster, young children may exhibit increases in aggressive and oppositional behaviors, separation anxiety, diminished activity levels, somatic complaints, and changes in sleeping behaviors, whereas adolescents tend to have elevated anxiety levels, diminished academic performance, and may engage in delinquent behaviors (Norris et al., 2002). It should be noted, however, that most children, even when directly impacted by disaster, do *not* develop new psychopathologies. Children can and do effectively adapt to disruptive shocks caused by disaster, especially when they receive appropriate support from a parent or other close adult and live in a safe and nurturing environment (Dubow & Tisak, 1989; La Greca et al., 2002; Masten, 2001).

Very little research has been conducted on the psychological effects of disaster on individuals with disabilities. Some policy accounts suggest that adults with disabilities experience feelings of distress, depression, or anxiety following disaster (Rooney & White, 2007), but most of these reports did not include a formal psychological assessment. However, a few studies on individuals with preexisting mental illnesses have found that when psychological treatment is continued postdisaster, patients do not acquire new psychopathologies, nor do their symptoms intensify (Bystritsky, Vapnik, Maidment, Pynoos, & Steinberg, 2000; McMillen, North, Mosley, & Smith, 2002).

Most children with disabilities are not only reliant on their parents for the same types of care as their peers who do not have disabilities but also often depend on their parents for additional functional and emotional supports. For instance, children with health care needs often have their parents administer prescriptions or perform medically related functions such as tube feeding or transferring them in and out of a wheelchair. Children with sensory disabilities such as blindness or deafness may rely on their parents for communication needs, and those with intellectual disabilities may need their parents to explain unfamiliar events when they occur. Yet trauma can have a deleterious impact on mothers and fathers and may limit their capacity to parent their children effectively (Appleyard & Osofsky, 2003). When parents suffer from depression, anxiety, posttraumatic stress disorder (PTSD), or other postdisaster disturbances, they are more likely to feel helpless and frustrated as they attempt to meet the support needs of their children (Osofsky, 1995), and severe parental distress can, in turn, contribute to PTSD symptomatology in children (Breton, Valla, & Lambert, 1993; Green et al., 1991). Given the added demands on parents of children with disabilities, it is possible that both these adults and their children could be at an even higher risk for postdisaster psychological impairment.

The separation of a parent and child during a disaster can be especially distressing to both the adult and child. For instance, one post-Katrina study found that trauma symptoms consistent with depression and PTSD were higher among children separated from caregivers during evacuation and displacement than among those children whose families remained intact (Osofsky et al., 2007). Because children with disabilities have social networks that tend to be smaller and more fragile (Smart, 2001), it is understandable that losing a parent or other person in their limited support system due to physical separation or even death could be particularly traumatic.

Research on individuals with disabilities suggests that they and their family members have more stressful evacuation and sheltering experiences and can be at a disadvantage in understanding instructions and procedures in these situations (Barile, Fichten, Ferraro, & Judd, 2006; Peek & Fothergill, 2008; White, 2006). Scotti et al. (2007) found that emergency situations, which typically include startling visual and auditory alerting systems and involve the presence of emergency personnel and other strangers, trigger negative stress reactions in adults with intellectual disabilities. Children with intellectual disabilities such as autism may become agitated by alert systems and postdisaster sheltering. Children are often excluded in terms of postdisaster communication and decision making (Mitchell et al., 2008), and children with disabilities may be especially prone to exclusion from information and services made available to other children in shelters such as recreation, crisis intervention, or different forms of therapy.

Due to their economic status, individuals with disabilities are more likely to live in areas that are at risk of physical impact during disaster (Hewitt, 2007; Wisner et al., 2004), and therefore it is probable that children with disabilities and their families will experience significant material loss. Proximity to a disaster and direct exposure to destruction, trauma, and loss, in turn, increases the likelihood that a child will develop PTSD (Garfinkel, Kaushal, Teitler, & Garcia, 2005; Norris et al., 2002; Weissbecker et al., 2008). In their posthurricane research, Van Willigen et al. (2002) found that a higher percentage of households that included an individual with a disability experienced damage to their homes, and that members of these households were more likely to report that their lives were still disrupted more than a year after the disaster. Given children's elevated risk for trauma following disaster, children with disabilities who are directly exposed to disaster may be more susceptible to long-term psychological disruptions and they may exhibit negative reactions years following the event (Christ & Christ, 2006). In addition, although research has yet to explore whether children with disabilities are at risk for experiencing recurring disasters, the compounded vulnerability of this population suggests that this may be the case.

Although research shows that most children can and do recover psychologically from disaster, children with disabilities may face additional barriers that may delay their recovery. In their analysis of survey data with New York City residents, Garfinkel et al. (2005) found that adults with work disabilities and children with activity limitations were among those most likely to report persistent mental and physical health problems 6 months after the 9/11 attacks. According to Stough and Sharp (2007), adults with disabilities are more likely to require accessible housing and social services postdisaster to support their disability-related needs as well as a substantially longer period of case management than do adults without disabilities. Following Hurricane Katrina, children with cognitive disabilities who were displaced from their home communities were placed on long waiting lists for psychiatric care. In addition, several parents noted that it was increasingly difficult or impossible for them to maintain their children's prescribed psychotropic medications, either because they could not find and afford appropriate psychiatric help or their medical records had been lost (Abramson & Garfield, 2006).

In a review of studies of child psychiatric interventions following disaster, La Greca (2001) concludes that when children are able to cognitively reprocess their traumatic experience, treatment of severe levels of PTSD is more successful. A challenge for children with cognitive disabilities, such as mental retardation or autism, is that they have difficulties in processing information, which may impede their psychological recovery postdisaster. Tierney et al. (1988) suggest that the social distancing associated with the label of "disabled" may further limit access to social networks and others sources of psychological support during a disaster. This same social distancing may also make it difficult for a child with a disability to adjust emotionally to a new school, neighborhood, or community.

Educational Vulnerability

Childhood is a time of rapid intellectual development, and thus children are uniquely vulnerable to negative educational outcomes that may accompany disaster (see Peek, 2008). Our search of the literature revealed limited research on the specific educational impacts of disaster for children with disabilities, likely because almost all of the extant literature on disability and disaster focuses on adult populations. The exception was Christ and Christ's (2006) post-9/11 study of children with learning disabilities. All of the children in their sample were living in one of the five boroughs of New York City at the time of the terrorist attacks and lost their firefighter fathers in the disaster. The researchers found that the children struggled with behavioral issues and increased educational demands after the disaster, although supportive special educators and school environments helped mitigate some of the most severe impacts of their losses.

The literature on the effects of disaster on children's education, in comparison, is much broader. Disasters often destroy school buildings, especially in locations where engineering standards and building codes are not enforced or where buildings are of less structural integrity: Hewitt (2007) inventoried tens of thousands of schools that collapsed in earthquakes over the past two decades in Pakistan, India, Nepal, Egypt, Turkey, Armenia, China, and other countries. The loss of schools may leave surviving children with few alternatives for an adequate education, and this issue may be especially problematic for children with disabilities as they face many barriers in accessing education during nondisaster times in both developed and developing countries (International Federation of Red Cross and Red Crescent Societies, 2007). When disaster disrupts a community's educational system, schools accessible to children with disabilities may be among the last to be rebuilt and ramps and other forms of access into inclusive schools may become a secondary priority.

After a disaster, teachers and other key school personnel who remain in the affected region may become overburdened and preoccupied with loss and increasing personal and professional demands (Osofsky et al., 2007). Educators may also become displaced, choose not to return to the community, or lose their jobs due to budget shortfalls (Casserly, 2006). The loss of experienced teachers and other typical supporters of children can be disruptive to children's academic progress, and may be especially challenging for children with disabilities. These children and their families often have complex support networks that include health care professionals, education specialists, psychologists, and other experts in their school district before disaster strikes. There is a chronic shortage of special education teachers worldwide, including in the United States, and replacing qualified educators in the postdisaster recovery period can be quite challenging. Competing demands for limited resources in disaster-affected school districts could further delay the hiring of these personnel. Students with disabilities can be highly sensitive to discontinuities in their educational services, and prolonged disruptions could ultimately diminish their long-term educational outcomes. Children with disabilities also tend to have challenges in establishing social relationships, and therefore may experience the loss of their educational support network more acutely (Smart, 2001).

Vital school records are often damaged or destroyed in a disaster, which can delay the enrollment of students in new schools (Picou & Marshall, 2007). Beyond their general school records, children with disabilities typically have extensive educational and medical records, as well as Individual Education Plans, that may be lost. The loss of these documents can pose significant challenges for new teachers who rely on diagnostic assessments of performance to recreate adequate educational plans for students with special needs.

Environmentally displaced children in developing countries are sometimes forced to stop attending school in order to assist with household chores or to participate in wage labor (Babugura, 2008). In the United States, children displaced by Hurricane Katrina suffered numerous educational challenges, including multiple school relocations, unstable family situations, and unwelcoming and hostile classroom environments (Fothergill & Peek, 2006; Picou & Marshall, 2007). Counselors and teachers who worked with Katrina-affected youth described worrisome behaviors in both elementary and secondary school students, including an inability to pay attention in class, disruptive actions, changes in their friendships, and increased risk taking (Osofsky et al., 2007). Individuals with disabilities are generally more vulnerable to dislocating events (Garfinkel et al., 2005). As a result, children with disabilities may be at special risk for educational delays, diminished academic achievement, or negative behavioral responses in the classroom.

Vulnerability and Resilience: Future Research Needs

Our overview of the relevant literature in two distinct areas of scholarship—one on individuals with disabilities in disaster, the other on children in disaster—points to a number of factors that may contribute to the physical, psychological, and educational vulnerability of children with disabilities in the context of disaster. Specifically, children with disabilities may be expected to show: higher poverty rates, elevated exposure to hazards, greater vulnerability in the context of traumatic loss or separation from caregivers, more strain on parents, and worse postdisaster outcomes unless special medical, familial, social, and educational protections are in place and vital social networks can be quickly reestablished. Consistent with a bioecological systems approach (e.g., Bronfenbrenner & Ceci, 1994; Cicchetti & Lynch, 1993), these factors are interactive and therefore create a *layering of vulnerabilities* that may place children with disabilities differentially at risk before, during, and in the aftermath of disaster.

This review has highlighted the potential vulnerabilities of children with disabilities in disaster as well as the social–ecological nature of that vulnerability. Due to the limited research on the effects of disaster on children with disabilities, our review has said little about the resilience of children with disabilities following disaster. Masten and

Obradovic (2008) have previously used resilience theory to examine how systems interact with individuals in disaster-related events and to delineate different patterns of individual functioning in the aftermath of disaster. In their conceptualization, resiliency refers to how individuals regain normal functioning following exposure to disaster and is described in terms of "recovery, bouncing back, normalization, or self-righting" (p. 9). When considering recovery postdisaster, we can anticipate that children with disabilities will follow one of Masten and Obradovic's patterns in which individuals enter the disaster impact stage already demonstrating a lower level of adaptive functioning. This suppressed level of functioning may also result from, as we have discussed, the interaction between the preexisting condition of the child with the external risk factors to which they were exposed predisaster. The developmental trajectory that children with disabilities will subsequently follow postdisaster, however, is less obvious.

Existing research illuminates the reliance of children with disabilities upon the broader macrostructure to protect them from disaster and it is likely that they will be equally dependent upon this same macrostructure to help them recover in the aftermath of disaster. Thus, when considering resilience postdisaster, we can predict that without a home that is physically accessible, a school system that provides appropriate academic modifications, or a town that has health services, many children with disabilities will no longer be able to successfully function within their own communities. Disability is thus both *magnified* and *amplified* through the interaction between the psychological or physical condition of the child with disabilities and the ongoing disruption of their environmental setting. When the postdisaster context no longer provides affordances for their disability, the individual functioning of a child with disabilities becomes more salient.

For these reasons, we see community recovery as a primary contributor to the resilience of children with disabilities following disaster. The more quickly essential services are restored within a community, the more likely children with disabilities and their families will be able to access needed supports and accommodations. Thus, the recovery of an individual child with disabilities may be closely connected to the recovery of the community macrosystem. In their community resilience framework, Norris, Stevens, Pfefferbaum, Wyche, and Pfefferbaum (2008) suggest that in order to increase their resilience to disaster, communities need to attend to their areas of greatest social vulnerability. Children with disabilities are one of these socially vulnerable populations, but we do not yet know what parts of the community infrastructure are most critical to support their resilience in the postdisaster context.

Given the dearth of empirical studies that actually explore how disaster affects children with disabilities in disaster, our review is necessarily speculative. Theoretically informed and methodologically rigorous quantitative and qualitative research is still needed to delineate the special risks and vulnerabilities that children with disabilities may experience both before and after disaster and to identify vital protective factors. Consequently, several key questions have not yet been addressed: How do various child characteristics (i.e., age, developmental level, intelligence, personality, gender, ethnicity, social class, family structure, geographic location) intersect with disability to influence the experiences of children with disabilities in disaster? How does disability type (i.e., auditory, visual, physical, cognitive) impact the ability of children with disabilities and their families to prepare for, respond to, and recover from different types of disaster? What roles do social stigma and institutional exclusion play in limiting the access of children with disabilities to emergency preparedness planning, sheltering options, therapeutic interventions, and other disaster-related resources? How are individuals within the social network of a child with a disability (e.g., parents, teachers, friends) affected by disaster and how does this influence the psychological response of the child? Are school-aged children with disabilities more likely to endure academic disruption, and if so, what are the developmental consequences of that disruption? What factors best support the resilience of children with disabilities postdisaster?

In order to design effective interventions for children with disabilities in disaster, future research needs to recognize the multilayered effects of how families, schools, communities, and societies shape the environment around children with disabilities as well as the types of adversity that they face during and following disaster (see Masten & Obradovic, 2008). In particular, we need to understand not only what makes these children vulnerable to disaster but also what can make them more resilient to disaster. Although disasters, at first glance, may appear to be what Lynch and Cicchetti (1998) refer to as *transient* risk factors, our discussion reveals them as potentially *enduring* vulnerability factors that represent ongoing conditions of inequity that place these children and their families at risk.

Given that children with disabilities often already face developmental challenges, disaster is one more risk factor that can lead to unfolding adverse consequences as these children develop.

All children, including those with disabilities, have the right to be safe and protected from natural and technological hazards and willful human-caused disasters. Certainly, children with disabilities should have equal access to disaster-related services as do their nondisabled peers, and in a just world, disability should not make them differentially at risk for injury, death, or psychological impairment following disaster.

Defining Best Practice in Care and Protection of Children in Crisis-Affected Settings: A Delphi Study

Alastair Ager, Lindsay Stark, Bree Akesson, and Neil Boothby
Columbia University

Thirty specialists in humanitarian work supporting the care and protection of children in crisis settings completed a 3-phase Delphi consultation. Proposals of best practice were elicited, reviewed, and rated by participants. A high level of consensus support was reached for 55 statements. These statements emphasized utilization of existing resources, participation, and inclusivity. The influences of resilience theory, social ecology, and cultural sensitivity were clearly evident. The utilization of developmental theory could be strengthened in relation to more differentiated understanding of the operation of protective influences and conceptualization of such influences in terms of "adaptive systems." Wider research engagement by development scientists in diverse cultural settings and clear formulation of findings for practitioners and policy makers would further support evidence-based humanitarian practice.

Globally, natural and man-made disasters represent a significant risk to children's developmental progress and well-being (Boothby, Strang, & Wessells, 2006; Bryce & Boschi-Pinto, 2005; Carballo, Heal, & Horbaty, 2006; Cohen et al., 2005). Estimates place the number of children involved in armed conflict at over 300,000 (Coalition to Stop the Use of Child Soldiers, 2004). During the Mozambican civil war, 64% of children aged between 5 and 15 years experienced abduction from their families and 77% witnessed murder (Boothby, Strang, et al., 2006). An estimated half million children, one fifth of the child population, were separated from their parents as a result of the Rwandan genocide (Cantwell, 1997). The 2004 tsunami orphaned well over 20,000 children, with estimates that approaching 40% of these were under the age of 5 (Carballo et al., 2006). Over 5,000 children were left without an adult caregiver in the immediate aftermath of the Sichuan earthquake (ReliefWeb, 2008). It is estimated that over 12 million children have been orphaned by AIDS in Sub-Saharan Africa (UNAIDS, 2004).

These global crises pose significant risks to children's well-being and developmental progress. Not only do children face increased vulnerability to their immediate physical well-being, but childhood development is often also compromised with serious risks for long-term growth and survival. These crises often result in decreased health and nutrition status among children, seriously impacting the important childhood years of physical and mental development. Childhood malnutrition has consistently been linked to growth stunting, cognitive deficits, and decreased school attendance (Berkman, Lescano, Gilman, Lopez, & Black, 2002; Hoddinott & Kinsey, 2001; Martorell, Rivera, Kaplowitz, & Pollitt, 1992; Mendez & Adair, 1999; Walker, Chang, Powell, & Grantham-McGregor, 2005) as well as increased morbidity and mortality rates (Bryce & Boschi-Pinto, 2005; Toole & Waldmen, 1997). The lack of primary caretakers' capacity to meet children's needs for care and support—be they missing, wounded, ill, or otherwise unavailable to provide their usual level of supervision—represents another consistent threat to developmental well-being (Levy-Shiff, Hoffman, &

The authors acknowledge the contributions of Deborah Tsuchida, Andrew McMahan, Ann Warner, Elisabeth Berger, and Mark Orr in the implementation of work described, and commentary on drafts of the manuscript provided by Ezer Kang, Pamela King, and Wendy Ager. Rosenthal, 1993; Williams, Hyder, & Nicoli, 2005). The importance of such factors as cognitive stimulation, caregiver sensitivity, responsiveness, and caregiver affect in supporting children's cognitive and socioemotional development highlights the risks to children in contexts of disaster of disruption to the protective environment of supportive caretakers (Brazelton & Sparrow, 2006; Walker et al., 2007; World Health Organization, 2004). Separation from caretakers also leaves children susceptible to exploitation and abuse (Hepburn, 2006).

From an ecosystems perspective, disaster and conflict alike erode the social fabric of communities, undermining the capacities and institutions that provide developmental support to children across varying ''ages and stages'' beyond immediate caregivers (Ahearn, Loughry, & Ager, 1999; Boothby, Crawford, & Halperin, 2006; Carballo et al., 2006). Crises disrupt the day-to-day activities that fill a child's life and which allow children to comfortably and safely explore and express themselves. In crisis settings, formal and nonformal systems of learning may be destroyed, seriously interrupting the opportunity for children's cognitive stimulation and critical thinking. Abduction results in disruption of schooling, social marginalization, and delayed advancement of economic livelihoods (Annan, Blattman, & Horton, 2006). In conflict settings in particular, disruption of civic and religious institutions may significantly threaten children's moral development and evolving spiritual practices (Wessells & Strang, 2006). All this represents major disruption of key adaptive systems (Masten & Obradovic, 2008) supporting developmental outcomes.

Given these threats, response to the well-being, protection, and developmental needs of children is a major component of contemporary humanitarian intervention in crisis situations. In 2007, UNICEF, the United Nations' lead children's agency, launched more than 50 distinct funding appeals (totaling US$874 million) to support humanitarian interventions addressing the protection needs of vulnerable children and women (UNICEF, 2008). To guide such work, a Child Protection Working Group (CPWG) has recently been established within the Protection Cluster Working Group, the principal coordination mechanism for United Nations and international nongovernmental organization (NGO) work in humanitarian crises (OCHA, 2007).

However, the evidence base for effective response in such circumstances is weak. The lack of rigorous empirical studies documenting the effectiveness of specific programmatic interventions is a consistent theme in the literature across a wide range of contexts (Ahearn, 2000; Boothby, Strang, et al., 2006; Brooks, 2005; Wessells, 2006; Williamson & Cripe, 2002). Repeated calls to implement more empirical evaluations of child protection and related programming have been made (Ager, Boothby, & Wessells, 2007; Leaning, 2001; Hofmann, Roberts, Shoham, & Harvey, 2004; Weinstein, 2005), but the complexity of crisis settings and the urgency of humanitarian response conspire against robust study design. Given limited human and financial resources, the rapid roll-out of services and interventions often takes precedence over research and evaluation efforts.

There are a number of recent examples of field data collection in crisis situations that suggest that these challenges are beginning to be successfully addressed (e.g., Annan et al., 2006; Betancourt, Pochan, & de la Soudiere, 2005). However, there are alternative strategies to establish a core knowledge base to guide intervention in a specific field that stand to complement such efforts. These are broadly known as *consensus methodologies* (Duncan, 2006).

Consensus methodologies build on the awareness that valuable knowledge is gained by supporting processes of reflection by professionals (Kolb, 1984; Schon, 1983). Experiential, reflective learning is an important source of knowledge for developing professional expertise. Humanitarian professionals have made much use of such reflection (Wood, Apthorpe, & Borton, 2001), developing a strong culture of interagency consultation to develop consensus guidelines on a range of issues (e.g., IASC, 2007; The Sphere Project, 2004). However, such consultations seldom adopt the rigor of established consensus methodologies, such as Delphi, which provide a highly structured means to distill key lessons learned by experienced practitioners across a range of settings (Bowling, 2002; Duncan, 2006; Jones & Hunter, 1995; Murphy et al., 1998; Walker & Selfe, 1996). Crucially, such methods provide a means to control the social and political processes that can otherwise distort the distillation of knowledge involved in developing consensus (essentially the under- or overweighting of specific elements of evidence as a result of status or other forms of influence).

The current study was an attempt to identify, through a Delphi consensus methodology, the core knowledge base that senior practitioners in the field of care and protection of children in crisis settings considered to constitute ''best practice'' at this time. We considered that seeking to determine such a knowledge base would serve two valuable functions. First, explicitly identifying areas where there is consensus and where it is currently lacking provides a sound basis for programmatic and policy reflection within the field. This can usefully involve both dissemination of program guidance (where there is established agreement) and focused debate (in areas of disagreement). Second, defining the knowledge base on which the field currently operates allows consideration of the extent to which this foundation effectively reflects relevant insights of developmental science and, further, the potential contribution of developmental research to enhancing such knowledge.

Method

Participants

We determined that the expertise most influential on current international humanitarian response to the care and protection needs of children was held by practitioners working with major agencies active in the field, with experience across a diverse array of settings, and accountable at a senior level (allowing significant influence on practice). Potential participants were therefore defined with respect to four criteria: (a) holding the most senior position in child protection within a leading donor agency working in the children in crisis field, (b) holding the most senior position within an international network or forum regarding children in crisis situations, (c) holding the position of senior child protection adviser or equivalent or above within specialized children's services within one of a specified number of "leading agencies" (intergovernmental organizations and international NGOs) working with children in crisis, and (d) having been employed/contracted by one or more of these "leading agencies" for technical/advisory work, leading to the production of five or more technical reports. "Leading agencies" were defined with respect to positions advertised and projects listed on the ReliefWeb and IRIN Web sites within the preceding year (a criterion that served to include all governmental and nongovernmental members of the CPWG of the Protection Cluster Working Group, the body mandated by the UN to coordinate work related to the care and protection of children in the context of disaster and associated humanitarian crisis).

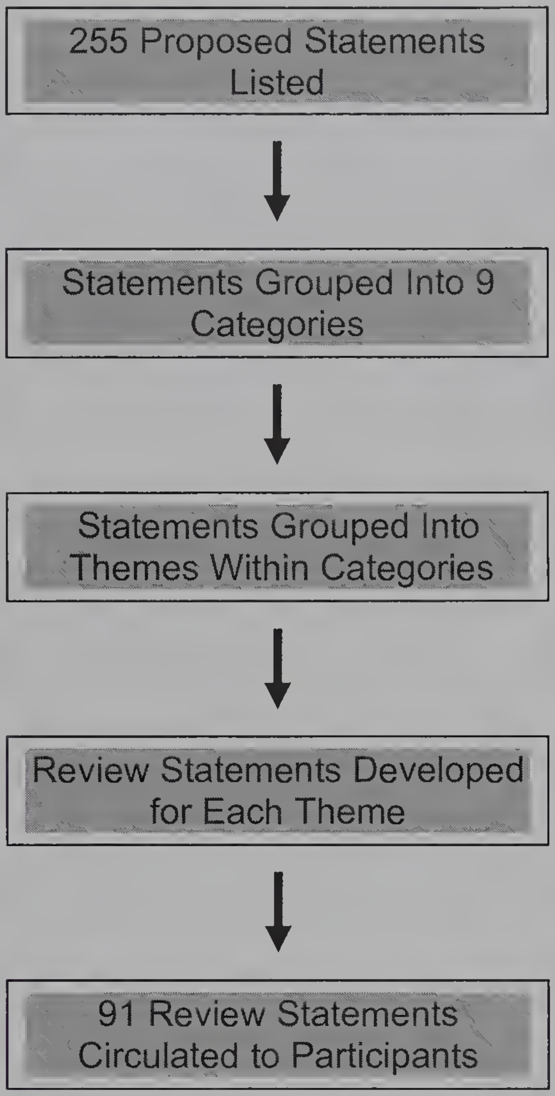
Seventy-seven potential participants were identified through Internet searches and telephone enquiry as fulfilling one or more of the above criteria. Contact by e-mail or telephone was established for 52 of these. Thirty-eight consented to enroll within the study and 31 completed Phase 1. Thirty participants completed Phases 2 and 3 of the study. Completing participants (21 women and 9 men) were drawn from all eligibility criteria, although there was a trend approaching significance ($\chi^2 = 6.90$, $df = 3$, $p = .075$) for more participants enrolled under latter criteria to complete the study (completion rates 10%, 17%, 30%, and 71%, respectively, for Criteria 1–4). Participants were thus more representative of technical and program design expertise than those responsible for decision making on funding.

Procedure

The study adopted a three-phase Delphi design (Duncan, 2006; Green, Jones, Hughes, & Williams, 1999; Hasson, Keeney, & McKenna, 2000). Additional phases may promote higher levels of consensus, but where attrition of participants is considered a risk—as it was here with an Internet-based consultation with senior practitioners—this may be at the cost of representativeness (Duncan, 2006; Hasson et al., 2000; Powell, 2002; Schmidt, 1997). The study was conducted between May 2006 and April 2007. Participants were regularly contacted by study administrators during this period to inform them on progress of the study and, where necessary, encourage timely completion of responses to allow the study to continue to the next phase.

Phase I: Elicitation of proposed best practice. Those consenting to enroll in the study were invited to propose, via e-mail, "best practice" in the care and protection of children in crisis-affected settings. Participants proposed such practice by submitting statements in a specified format. By the end of this initial consultation period, a total of 255 statements summarizing best practice had been submitted. A manageable, consolidated listing of statements for review in the next phase of the study was developed using successive thematic analysis (Silverman, 2001; see Figure 1 for a schematic representation of the stages followed).

First, three researchers independently reviewed a subsample of statements to develop preliminary categorical codes, which were then consolidated into the broad categories listed in Table 1. All proposed statements were then grouped into these categories. Second, two researchers independently analyzed statements within each category, grouping them to define constituent themes. An agreed set of themes within each category was then negotiated. Third, review statements were compiled to represent each of these themes. These review



255 Proposed Statements Listed

Review Statements Developed for Each Theme
91 Review Statements Circulated to Participants

Figure 1. Stages of thematic analysis to identify review statements.

statements were derived from listed statements, focusing on recurrent elements within each theme. Again, two researchers independently compiled statements and then negotiated agreed wording (targeting accessibility and lack of ambiguity). At least one statement was compiled for each theme; additional statements were compiled where themes represented five or more proposed statements and the initial statement drafted did not adequately represent key elements reflected in the theme. This resulted in a listing of 91 review statements.

Phase II: Preliminary ratings of proposed best practice. In Phase II, this listing was presented to all participants with the request to rate their level of agreement with each statement as *strongly agree, agree, undecided, disagree,* or *strongly disagree.* For each statement, there was also space for participants to enter comments related to their ratings.

Phase III: Finalized ratings of proposed best practice. In Phase III, the composite ratings of statements from Phase II were fed back to individuals, providing them with the opportunity to amend—or retain—their own ratings given knowledge of others' judgments. Participants were presented with a listing of statements indicating the percentage of participants who had marked *strongly agree, agree, undecided, disagree,* and *strongly disagree* for each. They were also shown the rating that they themselves had given for each statement and the comments provided on that statement by all participants. For each statement they then marked their final rating and made further comments on the statement as desired.

Results

Figure 2 summarizes the distribution of ratings across the 91 statements that emerged at the end of the third phase of consultation. As was to be expected with statements proposed as representing perceived "best practice," the distribution of ratings was positively skewed, with a median rating in the *strongly agree* range. Mean rating was 1.63, more than 3 times the standard error (0.395) from the center point of the 5-point rating scale.

Level of consensus was defined as the percentage of participants indicating *agreement* or *strong agreement* with a statement. Figure 3 displays the range of consensus support achieved across statements. Following emerging convention in Delphi studies (Beattie & Mackway-Jones, 2004; Brown, Crawford, Carley, & Mackway-Jones, 2006; Crawford, Mackway-Jones, Russel, & Carley, 2004; Duncan, 2006), 90% and 80% consensus were considered as potential thresholds to judge a statement as consensually agreed upon. With the gradient of this curve steepening beyond the 90% threshold, and then dropping sharply after the 80% threshold, the 90% threshold was taken as defining "clear consensus", with statements in the 80%–89% range designated as "approaching consensus."

Table 1 summarizes the level of consensus among participants for each statement. Statements are listed in descending order of consensus within each thematic grouping, and referenced by statement number and statement summary (listing of full statements is available at http://www.cpclearningnetwork.org).

Consensus is the key indicator for the interpretation of findings, but two other indices were calculated to support interpretation. Intensity ratios are commonly used in policy research to quantify the strength of opinion (including minority opinion) on Likert-type scales (Inglehart, 1995; Kemp & Burt, 2002; O'Hara & Stagl, 2002). Intensity ratios were

Table 1

Consensus Ratings of Reviewed Best Practice Statements

		Consensus (%)	AI	DI
Agency Strategy				
14	We must establish a "culture of learning" among agencies	100	0.60	0.00
11	Good practice requires attention to "Do No Harm" imperative	97	0.79	1.00
20	Child protection experts should be rapidly deployed to work with specialists in other sectors	97	0.78	0.00
13	Agency codes of conduct must be signed and enforced	96	0.86	0.00
17	Staff security must be considered at all times	96	0.82	0.00
18	Those delivering services to children must receive on-going support and training	96	0.57	0.00
4	Care and protection of children needs to be seen as concern of all agencies, working in an integrated, and coordinated manner	93	0.68	1.00
7	Coordination between agencies brings great benefits	93	0.54	0.00
9	We need to work at many levels, not just providing direct services	92	0.77	0.50
22	Advocacy needs to be data driven and based on program learning	89	0.64	0.00
3	Capacity building of local staff and partner organizations should be a component of all interventions	87	0.77	0.23
12	Consensus on definitions that relate to child care and protection is needed	87	0.39	0.77
8	It is good practice to build government capacity and avoid creating parallel systems	86	0.48	0.27
10	Documents, translated into all relevant languages, should be broadly distributed	83	0.28	0.59
15	Agencies need to balance investments between resident, IDP, and refugee populations and on both sides of civil wars	82	0.44	0.81
5	A rights-based approach must be continuously promoted	74	0.36	0.50
21	Failure to educate donors contributes to poor practice and lack of long-term commitment	71	0.35	0.38
6	Necessary protection and care actions are often broadly similar across situations. Good practice is having one set of guiding principles that are agreed to by all those involved in the care and protection of children	70	0.14	0.33
16	Effective protection programming must include nonviolent conflict resolution	61	0.30	0.36
19	Interventions need to be scalable	61	0.52	0.72
2	Emergency needs should be addressed independently of long-term strategy	33	0.39	0.85
Community Engagement and Participation				
27	In enabling community mobilization, it is vital to identify and include different community subgroups	100	0.77	0.00
23	It is essential to not ignore or undermine existing or traditional mechanisms	94	0.71	0.50
25	It is best practice to take a participatory approach with children and youth guiding the design, implementation, and evaluation of programs	93	0.43	0.50
28	It is good practice to conduct a participatory assessment with affected people in coordination with other assessment processes	93	0.68	0.00
29	We should support and foster development of preexisting child protection support networks	90	0.63	0.00
26	Children themselves are a neglected resource in child protection, and should be seen as social actors not as passive recipients of care and protection services	87	0.54	0.23
24	Best practice involves community-designed, community-managed, and community-owned projects	77	0.13	0.26
Understanding Children's Needs				
31	Programming should be inclusive and reach out to a range of affected children	100	0.47	0.00
35	Long-term strategies are required for youth who have missed education and who need to become economically active	100	0.50	0.00

Table 1

		Consensus (%)	AI	DI
37	First line action in protection is to limit exposure of children to traumatic events and provide activities that create sense of normality	96	0.45	0.00
32	Disaggregated data (by age, sex, etc.) are needed to ensure effective and appropriate programming	94	0.68	0.00
39	Agencies need to develop their skills for working at the community level in supporting families in caring for children	94	0.50	0.00
38	Children with extreme reactions to loss, displacement, etc. and those with severe mental illness should also be considered in program design and service delivery	93	0.46	0.00
36	Planning and delivery of services needs to be child-focused	90	0.33	0.00
30	We need to avoid categorizing and labeling children to avoid stigmatization and jealousy	76	0.68	0.13
34	Program assessments and interventions should consider children holistically and not in terms of sectors	73	0.38	0.11
33	Using the term "vulnerable" should be avoided	27	0.63	0.38
Monitoring, Evaluation, and Research				
40	We need to develop an evidence base of what constitutes effective child care and protection	100	0.83	0.00
46	We need strict ethical protocols for collecting information from children	100	0.72	0.00
43	It is good practice to evaluate program impact using a mixture of qualitative and quantitative data	97	0.72	0.00
45	Evaluation should consider project impact on social dynamics and power structures within communities	93	0.75	0.00
41	Effective programs must be able to demonstrate results with respect to clearly specified indicators and outcomes	93	0.48	0.50
42	Monitoring data should be used to adjust project implementation and evaluation data should be used to inform future planning	90	0.58	0.00
44	To assess impact we need rigorous data	69	0.20	0.32
Gender				
51	We need to provide "girl friendly" reproductive health and GBV services	100	0.82	0.00
48	Programs need to proactively reach out to engage girls	96	0.74	0.00
50	It is important to use local cultural resources as one means of supporting war-affected girls; it is equally important to be critical about practices which may violate human rights	96	0.61	1.00
52	There is a need for programming that targets and educates men and boys about gender roles and sexual responsibility	96	0.78	0.00
47	A gender perspective needs to be applied to all programming	93	0.77	0.50
53	We should avoid segregating girls into "appropriate for gender" skills training	86	0.42	0.21
49	We should support "positive discrimination" as one criterion to ensuring equitable treatment of girls	57	0.32	0.32
Separated Children				
58	We need to put strategies in place to prevent the separation of children	100	0.68	0.00
55	Understanding cultural norms can help protect children from exploitation	96	0.67	1.00
57	Thorough documentation is necessary for separated children before and during a crisis	96	0.41	0.00
62	It is best practice to monitor protection and well-being of separated children living with extended family or in foster care	96	0.78	0.00
59	Mobilization and mediation efforts are needed to facilitate the process of reintegrating separated children	93	0.61	0.00
60	Institutional care must be avoided whenever possible	89	0.61	0.00
56	Organizations need to be active in tracing separated children	85	0.46	0.50

92	Skills training programs need to include job placement, start-up funding or microcredit, and follow-up to be effective	86	0.37	0.21

Note. 90%+ participants indicating agreement or strong agreement. 80%–89% participants indicating agreement or strong agreement. AI = agreement intensity; DI = disagreement intensity.

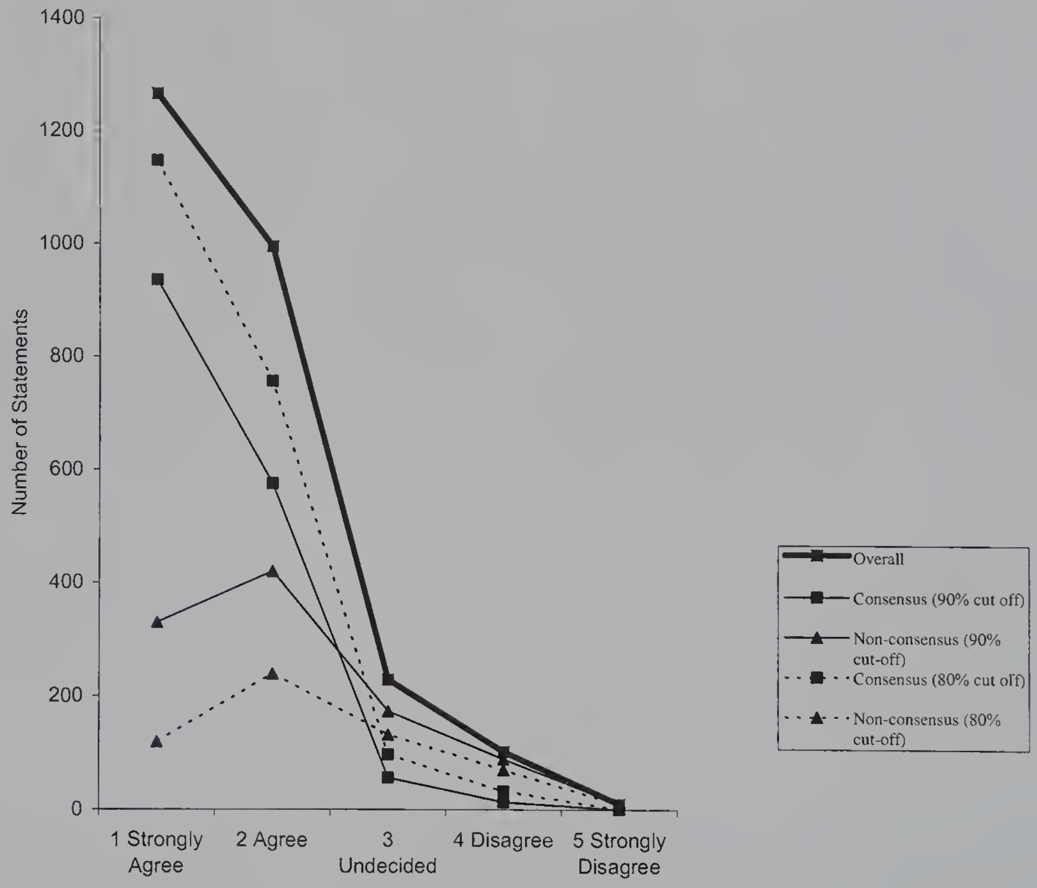

Figure 2. Frequency distribution of statement ratings (with differing "cutoff" thresholds for consensus).

therefore calculated to identify profiles of responding to particular statements that differed from the general pattern of response indicated in Figure 2. Agreement intensity (AI) was defined as the number of participants indicating strong agreement with a statement over the number of respondents indicating agreement or strong agreement with that statement. A score above 0.5 indicates that the pattern of agreements being more frequent than strong agreements (indicated by Figure 2 to be the modal pattern for nonconsensus statements) was not adhered to for this item. Disagreement intensity (DI) was defined as the number of participants indicating disagreement or strong disagreement with a statement over the number of respondents not agreeing (strongly or otherwise) with that item. It is a measure of the extent to which nonagreement involves genuine disagreement rather than uncertainty. A score of above 0.5 indicates that the modal pattern indicated by Figure 2 of responses of "undecided" being more frequent than explicit disagreement was not adhered to for this item.

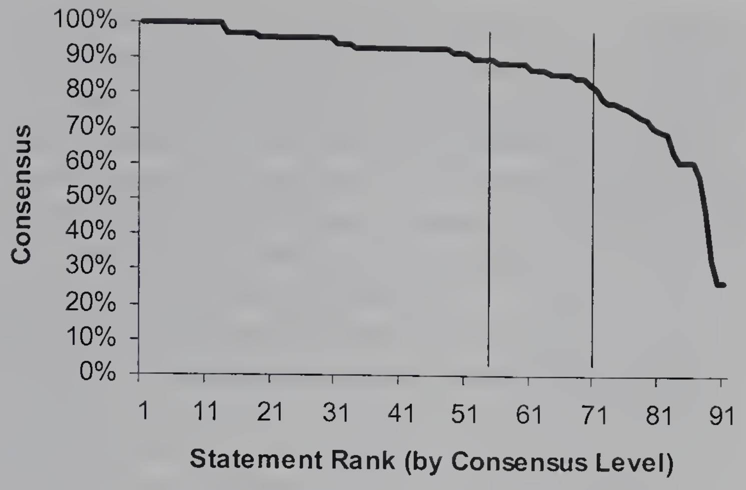

Figure 3. Levels of consensus support for statements (showing number of statements included by 90% and 80% thresholds).

Discussion

Constraints

As with all Delphi studies, the characteristics of the expert sample constrain the extent of generalization of findings. Here, the use of the Internet for identification of potential participants and of selection criteria related to "leading agencies" in the field of child protection in crisis settings provided a robust basis for inclusion of those shaping global debate in the field, but significantly underrepresents the potential contribution to such debates by "southern" child protection practitioners not visible by such means. Further, the high level of attrition of those participants meeting the inclusion criteria through their role with donor agencies urges caution in generalizing consensus to this constituency. For those meeting other inclusion criteria; however, retention of participants was high for Internet-based consensus studies (Elwyn et al. 2006; Hasson et al., 2000) and may be seen to fairly represent the technical and design expertise that shapes current programming.

The other major constraint related to the study design concerns the complex relation between statements about "best practice" and program practice in real settings. Statements were worded in a manner that sought to articulate concrete practice but, given the importance of context in determining details of implementation, they may often be seen as articulation of principle rather than defining practice per se. This leaves the statements open to differential interpretation across settings. Although the term best practice is used here to describe the intended focus of statements, the fact that such statements often articulate principles that remain open for somewhat differential implementation needs to be acknowledged.

Statements Securing Clear Consensus Support

The study identified 55 statements that secured clear consensus support (90% and above), which may be seen as representing a core knowledge base underpinning international response to child care and protection needs in crisis situations. A number of these statements reflect principles that have become established in guiding humanitarian efforts more widely including those related to the "do no harm" principle, agency coordination, staff codes of conduct and community participation (e.g., IASC, 2007; The Sphere Project, 2004). The majority, however, reflect understandings of the determinants of child well-being and development and, particularly, means of promoting this in contexts of crisis.

Participants share a view of the interconnectedness of child well-being and development with a wide range of social, cultural, and economic factors (Statements 4, 55, 76, and 87). Crises may directly expose children to trauma and loss (Statements 37 and 38), but the erosion of community resources also critically undermines well-being (Statements 23, 58, and 76). Targeted programming is supported in such areas as reproductive health services for girls (51), livelihoods programs for youth (91), documentation and tracing for separated children (57), and demobilization, disarmament and reintegration provision for war-affected youth (66). But the focus is generally not on direct service provision (Statement 9). The major emphasis is rather on utilizing, and where necessary rebuilding, community capacities (Statements 23, 29, 39, 50, 55, 59, and 88), and institutions (Statements 62, 79, 81, and 83). This involves a range of potential "adaptive systems," including kinship networks, schools, religious associations, and local healing rituals. Significant attention is paid to the manner in which interventions are planned and implemented. Active participation of children and youth (Statements 25 and 36) and the wider community (Statements 27 and 28) are considered crucial, and the inclusivity of programming (Statements 31, 32, 48, and 51) is consistently emphasized.

Statements Not Securing Clear Consensus Support

The 46 statements that failed to receive strong consensus fall into three major categories. First, there were 16 statements that secured agreement from between 80% and 89% of participants, and were considered "approaching consensus." These items generally appeared to fall short of clear consensus, either because they were considered somewhat conditional upon context (e.g., 3, 8, 10, 15, and 53) or referred to technical practices (e.g., 56, 67, and 77) that were not clearly understood by some participants.

Of rather greater interest conceptually—given the processes by which minority opinion can come to shape consensus over time (Moss & Schutz, 2001)—was a second group of items for which there was a lack of consensus but with some strong support (as indicated by an AI score of 0.50 or above, indicating that those in strong agreement equaled or outnumbered those in agreement). Four statements met this criterion: Statement 19 (regarding scalability), Statement 30 (regarding stigma), Statement 33 (regarding avoidance of the term ''vulnerable''), and Statement 65 (regarding cash settlements to children associated with fighting forces). The first of these statements was unique in attracting both a high AI and a high DI score, and is considered separately in the next section. The latter statements share a core concern: the danger of stigma and community disruption when inclusion criteria for programs are based on specific needs or exposure to specific experiences. Comments from participants suggested that these statements did not receive consensus support because of concern over targeting services. A caucus of participants was highly sensitive to the potential negative impact on community dynamics of explicitly discriminating between children on the basis of externally defined categories of ''vulnerability,'' suggesting: ''*vulnerable* is about the worst word to enter the vocabulary of development'' and ''vulnerability is a product of situations, not individuals.'' Given the prominent role of vulnerability in many conceptualizations of developmental risk (Daniel, Wassell, & Gilligan, 1999; Masten & Gewirtz, 2006), the use and application of the term in humanitarian settings clearly warrants further exploration.

A third grouping of statements not only failed to reach consensus but also were marked by strong opposition, as indicated by a DI score of 0.50 or above (those actively disagreeing with the statement equaled or outnumbered those who were undecided). Of statements failing to reach the 80% threshold level for consensus, four met this criterion (2, 5, 19, and 63). Statement 63 is essentially the converse of Statements 30, 33, and 65, and disagreement with it marks the same sensitivity to targeting support to a particular group, rather than providing communitywide supports. Comments suggest that Statement 2, addressing the balance of attention to emergency needs and long-term strategy—was ambiguous to many reviewers. By contrast, there were substantive concerns on the role of a ''rights-based approach'' (Statement 5). While a child rights framework (based on the Convention of the Rights of the Child; UNHCHR, 1989) has been adopted by a number of international humanitarian agencies, comments here principally addressed the operationalization of this approach:

> Narrow definitions happen too often. It can inspire unbalanced approaches, and can undermine capacity-building.

> . . . only if done without imposing rights or taking a moralistic stance, demeaning local practices.

Finally, as noted above, Statement 19 (interventions need to be scalable) was unique in attracting both AI and DI scores of above 0.50, suggesting strong, divided opinion on this issue. Comments ranged from the strongly supportive:

> Great interventions that do not reach the vast majority cannot be considered effective practice.

to those arguing that scalability was not an appropriate criterion for effective practice:

> The fact that interventions can't be applied beyond a small group should not necessarily preclude those interventions being carried out.

Such disagreement suggests quite different understandings of the mandate of humanitarian assistance to children in situations of crisis. Seeing child care and protection in emergencies alongside such interventions as water and sanitation provision, food distribution, and emergency health care encourages a populationwide, community-based approach, with an expectation of general coverage and thus ''scalable'' provision (Brainard & LaFleur, 2007). Intensive, focused, relatively high-cost interventions draw upon radically different programmatic assumptions.

Humanitarian Consensus and Developmental Science

Few participants—either through the provision of statements or subsequent commentary on ratings—explicitly framed best practice regarding child care and protection in crisis settings in developmental terms. However, best practice was seldom cited in the narrow terms of immediate protection during crisis alone; attention was consistently paid to the longer term trajectories of children and the impact on these of crisis experiences, and the related erosion of local capacities and institutions. Explicitly acknowledged or not, practitioners in such work are seeking to shape developmental outcomes and are making assumptions about processes of development.

Three questions follow from this. First, what ideas from developmental science does this knowledge base principally draw upon? Second, are there currently unutilized insights from developmental science that would usefully inform humanitarian response to children in crisis settings? Third, how might our findings shape the work of developmental scientists eager to impact humanitarian work with children?

The current knowledge base informing humanitarian response reflects most significantly the influence of two developmental constructs: those of *resilience* and of *social ecology*. Luthar and Cicchetti (2000) identify three distinguishing features of the construct of resilience: a focus on positive outcomes and not just negative ones, an emphasis not only on deficits but also of strengths, and consideration of the impact of the interplay of vulnerability and protective factors. These features were strongly reinforced throughout the statements achieving consensus. The concern of some participants in ascribing vulnerability to individuals rather than circumstances (Statement 33) reflects broader thinking on resilience being seen as a process rather than a personal characteristic (Luthar, Cicchetti, & Becker, 2000; Masten & Wright, 2009). In terms of Buckner, Mezzacappa, and Beardslee's (2003) distinction between inner resources (e.g., self-esteem, intellectual ability) and external resources (e.g., social support, relationship with caregiver) supporting resilience, it is clear that the latter receive much more attention in framing programmatic response. Participants generally drew much more comfortably upon social constructs than psychological ones, and although this may reflect uncertainty regarding the validity of psychological constructs across cultures (IASC, 2007), it also appears a pragmatic response given the available intervention modalities and resources in most humanitarian emergency settings.

This emphasis reflects also the influence of social ecological constructs on identified best practice. Such analysis—based on conceptualizations stemming from the work of Bronfenbrenner (1979)—has been widely promoted as an appropriate conceptual framework to shape humanitarian response to children in crisis settings (Boothby, Strang, et al., 2006; Wessells, 2006). It emphasizes how "children develop in a social milieu in which family, peers, teachers and the wider community are part of the fabric of their day-to-day lives" (Kostelny, 2006, p. 25). In this study, this emphasis was most clearly evident in support for the reunification of children with families or other culturally appropriate carers, but was also reflected in encouragement for the prompt reinstitution of schooling (Statement 79) and the prioritization of strengthening "traditional mechanisms" (Statement 23) and wider community activities and institutions.

Although we can identify themes of resilience and social ecological analysis shaping proposed best practice in child care and protection in crisis settings, utilization of such concepts was generally underdeveloped. For example, best practice statements tended to use "protective" factors and "resilience" as a general "shorthand" for strengths that can be capitalized upon. However, useful distinctions have been made in the resilience literature in the way that factors beneficially influence outcomes. *Promotive factors*, for instance, are beneficial in all circumstances, whereas *protective factors* show benefit in circumstances of risk (Masten & Wright, 2009). Luthar et al. (2000) distinguish factors that do not enhance functioning but reduce its deterioration (protection stabilizing), a key function in crisis settings. Factors that may lead to enhanced functioning (so-called flourishing; see Keyes, 2007) on transition into crisis (protection enhancing) have also been the focus of much interest (Luthar et al., 2000; Masten & Obradovic, 2008). These conceptualizations are not a matter of theoretical elegance; they are potentially of major programmatic significance. In the immediate wake of crisis, for instance, factors having a "protection-stabilizing" effect will usually be most important to identify and promote. In subsequent phases of recovery, more directly protective influences might appropriately be fostered.

Recent developments in the field of *development systems theory* also offer potentially valuable insights for humanitarian assistance to children. Lerner (2006) uses the concept of "adaptive developmental regulation" to refer to the two-way interaction between individuals and the many "layers" of their context, and suggests that the aggregate of multiple interactions shapes developmental outcomes. Reviewing four decades of research on resilience, Masten and Wright (2009) conclude the recurrent implication of certain basic human adaptive systems assumed to have been shaped through processes of biological and cultural evolution. Such formulations shift attention from linear "factors" promoting development to nested systems that serve this function. Masten and Obradovic's (2008) grouping of such systems into those promoting "human capital" and "social capital" has certain parallels with formulation of resource domains relevant to psychosocial support in humanitarian settings (Ager, Strang, & Abebe, 2005). This distinction offers encouragement to mobilizing adaptive systems of attachment and agency (reflecting the domain of "human capital"), as well as of family, peer and cultural systems (reflecting the more familiar territory for humanitarian work of "social capital"). The focus on identification, and mobilization, of adaptive systems that support development also has powerful synergies with moves to establish a more systemic approach to child protection work in crisis settings (PFMH, 2008; UNICEF, 2008).

There is a third area where humanitarian practice might benefit better from developmental theory. Explicitly developmentalist conceptions shaped much writing on humanitarian interventions with children in the later decades of the 20th century, principally from a perspective of child psychology (e.g., Garbarino, Kostelny, & Dubrow, 1991; Hundeide, 1991; Jareg, 1987). Although developmental psychology currently has a less prominent role than formerly within developmental science, the latter retains sensitivity to issues of developmental transition. However, there was remarkably little emphasis in the reported statements on such matters. The term *age*, for example, was cited only once (although it was stated as a basis for disaggregation to ensure appropriate programming response; Statement 37). The support given to schooling may be taken as some recognition of the value of this institution to structure children's experience in a developmentally appropriate way, but there was otherwise little explicit attention paid to programming to be shaped to specific "ages and stages." The move from school to work and the value of vocational training was the only developmental transition to which explicit attention was paid (Statements 35, 81, 84, and 91), potentially reflecting the concerns—particularly in conflict settings—of the vulnerability of disengaged youth to recruitment and illegal activity (Stark, Boothby, & Ager, 2009). Beyond the asserted role of restoring stable caregiving, there was no recognition of the specific needs of preschool children, for example, reinforcing other observations calling for a more explicit consciousness of early childhood intervention needs in humanitarian contexts (CGECCD, 2008). Such interventions may be particularly important given the potential for "cascading": early developmental progress providing a crucial foundation for subsequent developmental challenges (Masten & Wright, 2009).

What are the implications for developmental scientists of the findings of the current study? We suggest that there are two major themes that warrant exploration. The first of these is responding to the issue of culture and, specifically, cultural variation. Developmental scientists have increasingly recognized the "culture bound" nature of much contemporary analysis. For example, Weisz, Sigman, Weiss, and Mosk (1993) have argued that data suggest that "core tenets of attachment theory are deeply rooted in mainstream Western thought and require fundamental change when applied to other cultures or minority groups." Rothbaum, Pott, Azuma, Miyake, and Weisz (2000) conclude that "findings from research on parent–child and adult mate relationships suggest that there are different paths of development in Japan and the United States" noting that "the notion that there are different paths of development challenges Western investigators' presumption that certain processes . . . are central in all relationships" (p. 1121). Pena (2007) has noted the challenge of ensuring the linguistic, functional, cultural, and metric equivalence of measures used across contexts. Tudge et al. (2006) have demonstrated the wide cultural variation—and its interaction with class—in the behavior of 3-year-olds attending and not attending day care.

In the face of such evidence, it is not surprising to see humanitarian practitioners reluctant to draw lessons across settings. Participants failed to consensually endorse "necessary protection and care actions are often broadly similar across situations" (Statement 6), adding such comments as "one size never fits all," "approaches should not be cookie cutter," and "globalized standards that bear little relation to local realities are likely to be problematic." Concerted critique over recent years of models that insufficiently recognize the socioeconomic and cultural embeddedness of child well-being (Ahearn et al., 1999; Bracken, Giller, & Summerfield, 1995; Wessells & Monteiro, 2004) has clearly established cultural sensitivity as a dominant lens through which issues of children's development is viewed.

But there is a tension in the approach commended by senior practitioners, as elsewhere there are calls for a stronger "culture of learning" (Statement 14) and more evidence-based advocacy (Statement 40), both requiring some capacity for generalization. There are, as one participant noted, clear challenges with adopting a "blank sheet" approach in settings of acute crisis and vulnerability.

What humanitarians require is a conceptualization of developmental processes that is sufficiently robust to formulate consistent sources of influence on developmental outcomes, without presuming upon their necessary form. In other terms, the practice of humanitarian assistance in diverse cultures requires sensitivity to indigenous psychologies and *emic* perspectives (Kim, Yang, & Hwang, 2006). But it also requires some derived *etic* understandings in order to respond in a timely and strategic manner, drawing global lessons from the experience of, and recovery from, crisis. Providing a basis for such understandings is a great challenge for developmentalists (Rothbaum et al., 2000). But it is a challenge worthy of the aspirations of contemporary developmental science. As Lerner (2006) suggests, "developmental science that is devoid of knowledge of the individual and group ranges among diverse groups, and that is devoid of knowledge of the range of assets in diverse contexts, is an incomplete developmental science" (p. 12). To develop theory and conceptualization fit for application to diverse settings will require engagement with a far broader range of contexts than is currently reflected in the pages of leading journals. Development science must be an increasingly global enterprise, with commitment to research partnerships with "southern" institutions and use of methodologies suited to unstable and resource-poor settings (PFMH, 2008), prerequirements of effective "reach" into the required diversity of development contexts.

Second, theory and evidence needs to be presented in forms that are accessible to policy makers and practitioners, and related to the decisions and actions they face regarding child care and protection in crisis. The strong endorsement of (and frequent reference to) the injunction to "do no harm" (Statement 11) may be welcomed as a recognition of cultural sensitivity and the frequent imbalance of power when working in crisis-affected settings. But it may also be seen as testament to the lack of clear, confident guidance from developmental science regarding key developmental processes (leaving workers, as participants variously noted, "paralyzed" or "with their hands tied from doing even the most basic of psychosocial work").

Luthar and Cicchetti's (2000) 10 "Guiding Principles in Applying the Resilience Perspective Toward Developing Interventions and Policies" provide a good illustration of how developmental science may be presented for practitioner audiences. These principles are of a form not unlike the presented statements here, and with much convergence (e.g., "interventions should target salient vulnerabilities and protective processes that operate across multiple levels of influence" cf. Statement 9; "intervention efforts should aim at fostering services that eventually can become self-sustaining" cf. Statement 23; "interventions must be designed not only to reduce negative influences but also to capitalize on specific resources within particular populations" cf. Statement 25). If developmental science can formulate its findings and implications in such terms, humanitarians are far more likely to reflect such thinking in their programming decisions.

In conclusion, this study suggests significant consensus amongst senior practitioners regarding "best practice" in the care and protection of children in crisis settings. This knowledge base reflects the influence of conceptualizations of social ecology and resilience, but greater use could be made of developmental science in relation to more sophisticated understandings of the manner of "protective" influences, particularly in relation to their being formulated as the reflecting the operation of core human adaptive systems. Some issues that failed to secure consensus support (e.g., regarding expectations of the scalability of interventions and the use of the concept of vulnerability), signal key issues for debate in the field at this time. For developmental scientists to constructively contribute to such debate a more extensive research engagement in diverse cultural settings (including those experiencing crisis) is required, accompanied by clear formulation of guidance for practitioners and policy makers.

Dogs, Bogs, Labs, and Lads: What Phonemic Generalizations Indicate About the Nature of Children's Early Word-Form Representations

Erik D. Thiessen
Carnegie Mellon University

Meagan N. Yee
Indiana University

Whereas young children accept words that differ by only a single phoneme as equivalent labels for novel objects, older children do not (J. F. Werker, C. J. Fennell, K. M. Corcoran, & C. L. Stager, 2002). In these experiments, 106 children were exposed to a training regime that has previously been found to facilitate children's use of phonemic contrasts (E. D. Thiessen, 2007). The results indicate that the effect of this training is limited to contexts that are highly similar to children's initial experience with the phonemic contrast, suggesting that early word-form representations are not composed of entirely abstract units such as phonemes or features. Instead, these results are consistent with theories suggesting that children's early word-form representations retain contextual and perceptual features associated with children's prior experience with words.

From early in life, children are able to remember words; they recognize words after familiarization (e.g., Jusczyk & Aslin, 1995) and look at the appropriate visual referent of spoken words (e.g., Fernald, Pinto, Swingley, Weinberg, & McRoberts, 1998; Tincofff & Jusczyk, 1999). But speech presents a representational challenge because of its variability. The same word can be produced with different rates, fundamental frequencies, amplitude, and formant structure both within and across speakers. Learners must represent words in a sufficiently flexible manner that two different utterances of the same word can be mapped to the same meaning. But at the same time, representations must be conservative enough that learners can determine when they are hearing a novel word (as when a child who knows *dog* hears *bog* for the first time), as opposed to a novel production of a familiar word. This is likely to be especially challenging for infants and young children, whose knowledge of the phonological system of their native language is in a state of flux (e.g., Werker & Tees, 1984).

One approach to this representational problem suggests that speech is mapped on to abstract, invariant representations (e.g., Nearey, 1997). For example, in traditional linguistic theory (e.g., Chomsky & Halle, 1968) representations of word forms in the mental lexicon are constructed from abstract, invariant phonological components such as phonemes or features (e.g., Nearey, 2001; Prince & Smolensky, 1997). These components are identical across different surface realizations: the same features are activated by the [d] in *dog* and the [d] in *lad*. According to this approach, listeners must factor out the surface variability of speech to access the abstract units that compose the word. There have been several proposals as to how this might be accomplished, including perceptual normalization accounts (e.g., Shankweiler, Strange, & Verbrugge, 1977) and articulatory theories (e.g., Browman & Goldstein, 1986, 1992; Repp, 1982). These proposals, and others, share the assumption that surface variability, such as speaker-specific indexical properties, is noise that must be discarded before listeners can identify abstract, phonological units of representation.

An alternative approach suggests that the surface variability of speech is not discarded but instead remains part of the long-term representation of word forms from early in development (e.g., Werker & Curtin, 2005). This approach is consistent

with demonstrations that listeners recognize recurring words more easily when they are produced by the same speaker, indicating that indexical information is encoded in representations (e.g., Bradlow, Nygaard, & Pisoni, 1999; Goldinger, 1996). One way listeners might encode surface variability is to store multiple exemplars of words rather than a single abstract and canonical version (e.g., Goldinger, 1998; Jusczyk, 1993). Such information may be sufficient for word recognition alone, or it may be incorporated in parallel with more abstract representations (e.g., Hanson, 1977; Remez, Fellowes, & Rubin, 1997). Even very young learners may have access to both kinds of representations. Research on categorical perception (e.g., Eimas, Siqueland, Jusczyk, & Vigorito, 1971) and vowel change detection in the face of speaker differences (Kuhl, 1983) suggest that infants can respond to acoustic differences that reflect linguistically relevant distinctions, such as phonemic categories, in the face of surface variability. At the same time, however, infants appear to encode speaker-specific properties of their experience with words (Houston & Jusczyk, 2003), and respond to acoustic differences between exemplars of a single phonemic category (McMurray & Aslin, 2005).

In the adult state, an abstract approach and approaches that incorporate surface variability in representations make similar predictions. For example, connectionist models can learn, through exposure to variable input, to respond to the same phonemic distinctions as models relying on more abstract representations (e.g., Vallabha, McClelland, Pons, Werker, & Amano, 2007). However, these two kinds of representational approaches lead to very different predictions about the rate of learning and generalization. In a theory where generalization occurs automatically at the level of abstract phonemes, a child who responds to [d]—as distinguished from [t]—has mapped the spoken realization of those phonemes onto representations abstracted from their acoustic idiosyncracies. Because these representations are abstract, they should generalize to a variety of novel acoustic instances. A learner who responds to the contrast followed by the vowel [i] should respond to the contrast in the same way when it is followed by the vowel [a]; even though the acoustic realization of [d] is different in *da* than *di*, the underlying representation is identical. Similarly, a contrast available in syllable-initial position should be available in syllable-medial or syllable-final position, insofar as the contrast can be mapped onto identical representations.

These kinds of abstract approaches predict very rapid patterns of developmental acquisition. Shvachkin (1948/1973)—working from an acoustic framework—argued that once children master the use of a particular phoneme, it should be available in every context in which the native language employs that phoneme. More recent theories have made similar predictions. For example, Lindblom, Diehl, Park, and Salvi (2008), whose work emphasizes a more articulatory approach, predict that "**once a target** [place feature] **has been learned in one context, it can be immediately re-used in other contexts**." (bolding in original). This powerful generalization is one of the strengths of an abstract representational system (e.g., Berent, Marcus, Shimron, & Gafos, 2002), as it can potentially explain the rapidity, and consistency across a variety of differing environments, with which children acquire language (for discussion, see Lindblom, Diehl, Park, & Salvi, in press). By contrast, a representational system that encodes multiple aspects of the surface variability of a contrast should lead to less inclusive generalization in early learning. Because the acoustic realization of a phonemic contrast is different across different word positions and vocalic contexts, a contrast that is productive in one setting may not be productive in all settings. Instead, generalization on this kind of account should be based, at least in part, upon the similarity of the current instance to prior experience (e.g., McClelland & Elman, 1986). Further, the frequency with which a learner experiences a contrast in a particular context should be important; if the [d]–[t] contrast is more common in word-initial position than in word-final position (e.g., Zamuner, 2009), a learner might initially respond to contrast more successfully in word-initial position (e.g., Schafer & Mareschal, 2001; Storkel, 2001).

Note, however, that theories proposing an abstract representational system need not predict invariant responses to every instance of a phoneme. For example, in word recognition, different realizations of the phoneme may be more or less effective in activating the phonemic representation, as is the case when an ambiguous articulation is heard (e.g., Norris & McQueen, 2008). Similarly, in phonotactic learning, a particular phoneme may occur in some word positions or syllabic contexts, but not in others (e.g., Hayes, 2004). More generally, it is well known that distinctions at a perceptual level need not correspond with distinctions at a phonological level (e.g., Dietrich, Swingley, & Werker, 2007; Pallier, Colome, & Sebastian-Galles, 2001; Stager & Werker, 1997). Indeed, even in early childhood, there is evidence that children's sensitivity is graded as a function of the tasks in which they are tested. Children will use a distinction in a word-recognition task—as when distinguishing between familiar words like *ball* and *doll* (e.g., Fennell & Werker, 2003; Swingley & Aslin, 2000)—that they fail to use in the context of associating a novel label with a novel object (Pater, Stager, & Werker, 2004). These complexities make it particularly important to explore generalization in the context of word–object association. Simply because infants generalize in a perceptual task (e.g., Maye, Weiss, & Aslin, 2008) does not necessarily indicate that they will do so when representing word forms. Conversely, the fact that learners generalize conservatively when learning phonotactic regularities (e.g., Prince & Tesar, 2004) does not require that they will do so when learning words.

To distinguish theories where generalization occurs at the level of abstract phonemes, or context-free features (e.g., Dinnsen, O'Connor, & Gierut, 2001; Nearey, 2001), from perceptually based accounts (e.g., Houston & Jusczyk, 2003; Ryalls & Pisoni, 1997; Singh, 2008), it is critical to assess the course of learning in a task relevant to lexical development. Learning should be rapid and highly generalizable if children's representations are abstract, slower and more conservative for representations that incorporate subphonemic and indexical information (cf. McClelland & Patterson, 2002). One important component of word learning is the ability to associate labels with objects, an ability that can be assessed experimentally (e.g., Stager & Werker, 1997). Such assessments indicate that young children have difficulty differentiating between novel labels that differ by only a single phoneme (such as *bih* and *dih*), although they can learn to do so successfully (Thiessen, 2007; Yoshida, Fennell, Swingley, & Werker, 2009). In this series of experiments, we will assess how widely children generalize their learning about phonemic differences in a word–object association task.

Using the difference between words that differ by a single phoneme (i.e., minimal pair words such as *bog* and *dog*) in a word–object association task is difficult for children in the first half of their 2nd year of life (e.g., Shvachkin, 1948/1973; Stager & Werker, 1997). Upon learning a label for a novel object (such as *bin*), children of around 14 months of age accept a wide variety of minimal pairs of that word (e.g., *pin* and *din*) as labels for the novel object (Pater et al., 2004). This is not due to an inability to hear the phonemic distinction. When tested on the same contrasts with known words (such as *ball* and *doll*), children are responsive to the identical contrast (e.g., Fennell & Werker, 2003; Swingley & Aslin, 2002). Instead, children appear to have difficulty using phonemic contrasts in the context of associating novel labels with novel objects. The ability to use phonemic contrasts to differentiate novel labels improves with development. By 17 months, children are beginning to behave more like adults: After they have learned a label for a novel object, they reject alternative labels that differ on one or more phonemes. At 14 and 17 months, the ability to do so is related to vocabulary size; by 20 months, this is no longer the case, perhaps because by this age virtually all children have exceeded the threshold of vocabulary necessary to succeed in the task (Werker et al., 2002).

The relation between vocabulary and performance on the switch task posited by Werker et al. (2002) suggests that linguistic experience influences children's use of phonemic contrasts in when learning words. This would explain why children with larger vocabularies were more successful in the task. Consistent with this hypothesis, computational modeling indicates that experience with words may affect the way that children respond to phonemic contrasts (Schafer & Mareschal, 2001), and both 17- and 20-month-olds know far more words than 14-month-olds (Fenson et al., 2002). In particular, children in this age range know relatively few minimal pair words (e.g., Caselli et al., 1995; Charles-Luce & Luce, 1995). For example, Swingley and Aslin (2007) found that, in a sample of 18-month-old Dutch-learning children, over two thirds of the words in children's vocabularies had no minimal pair neighbors. The majority of the words with which children become familiar between 14 and 20 months provide examples of phonemes distributed in different lexical contexts: [d] in *doggy* and *daddy*, [t] in *teddy* and *tiger*.

Thiessen (2007) demonstrated that exposure to phonemes in different lexical contexts ([d] in *dawbow* and [t] in *tawgoo*) facilitates children's use of the phonemic contrast in a word–object association task. This may be related to the phenomenon of acquired distinctiveness: When two similar stimuli, A and B, are paired with two highly discriminable associates X and Y (forming compound stimuli AX and BY), the distinction between A and B is heightened (e.g., Hall, 1991). Children's familiarity with an increasing number of words in the 2nd year of life, very few of which are minimal pairs, may provide evidence that different phonemes are paired with different lexical forms in the language and facilitate use of the distinction between them

(Thiessen, 2007). This would explain the observed correlation between vocabulary size and use of phonemes in word–object association tasks (Werker et al., 2002); children with larger vocabularies have more evidence about the distribution of phonemes in their language. From the perspective of exemplar-based theories, these results can be explained in terms of variability among exemplars facilitating generalization (e.g., Hintzman, 1986; Rost & MacMurray, 2009). From the perspective of theories emphasizing more abstract representational systems, or parallel encoding of acoustic and abstract information (e.g., Remez et al., 1997), success on the task might indicate a shift to more abstract encoding. For example, Werker and Curtin (2005) suggest that while children's representations contain rich acoustic detail, children must weight the phonemic aspects of these representations more heavily to succeed in word-learning tasks relying on a single phonemic distinction.

As such, while the results of Thiessen (2007) indicated that exposure to phonemes in different lexical contexts improves children's abilities to use the contrast between phonemes, those experiments were ambiguous with respect to whether children learned about abstract, readily generalized contrasts (i.e., phonemes or features). The current series of experiments systematically assessed how widely infants generalize a contrast (such as [d] vs. [t]) after they have been exposed to stimuli that should facilitate their use of the contrast in a word–object association task. If children encode speech abstractly, generalization should be rapid and pervasive: Once a child has identified the [d]–[t] contrast in one context, it should be available in many (or even all) contexts (e.g., Lindblom et al., 2008; Shvachkin, 1948/1973). By contrast, if children encode subphonemic or indexical information, generalization may be much more limited, especially early in learning (e.g., McClelland & Patterson, 2002). Children should initially be most likely to use the [d]–[t] contrast in a context they have previously experienced, and less likely to use it in contexts that differ from the original context. Conversely, training in a different context should allow children to succeed in contexts where they have previously failed, as is demonstrated in Experiment 3.

Experiment 1

Fifteen-month-olds fail to respond to differences in minimal pair labels in a word–object association task (e.g., Pater et al., 2004; Shvachkin, 1948/1973). Thiessen (2007) found that exposing children to words in which phonemes occurred in clearly distinct lexical contexts—as [d] and [t] in *dawbow* and *tawgoo*—facilitates their use of the distinction between minimal pairs. However, these results are inconclusive with respect to the degree of specificity or abstraction of children's learning. Children were tested with the syllables *daw* and *taw* after exposure to the words *dawbow* and *tawgoo*. Therefore, children could potentially have learned about a feature contrast (voicing), a phonemic contrast ([d]–[t]), or a contrast in a specific syllabic context (*daw* vs. *taw*). If children learned about voicing, this knowledge should generalize to a wide variety of contexts. By contrast, if infants learned about the specific syllables, then their generalization should be limited. Similarly, most prior experiments testing children's use of phonemic contrasts expose participants to phonemes in only one particular context, making it difficult to assess how generalizable children's representation of these contrasts might be (e.g., Stager & Werker, 1997).

Our goal in this experiment was to assess how widely children generalize the contrasts they use in word–object association tasks. To do so, we exposed children to the same training regime used in Thiessen (2007): Children learned the names of three objects. The labels of two of these objects provided evidence of phonemes ([d] and [t]) occurring in distinct lexical contexts: *dawbow* and *tawgoo*. The third object was labeled *yad*. After learning the names of these three objects, infants were presented with test trials in which the third object was paired with its original label (*yad*), or a novel minimal pair label (*yat*). Experience with *dawbow* and *tawgoo* enables children to differentiate between *daw* and *taw* test trials in this procedure (Thiessen, 2007). If children have learned about a phonemic contrast, or a featural contrast (voicing), this learning should generalize to a novel word position (from [d]-[t]aw to ya[d]-[t]). By contrast, if children's learning is more specific, and tied to the particular exemplars with which children have prior experience, then exposure to *dawbow* and *tawgoo* would not be as informative with respect to *yad* as it is with respect to *daw*, and children may fail to use the contrast between [d] and [t] in word-final position.

Method

Participants

Participants were 16 toddlers (half female; 13 Caucasian, 2 Asian, and 1 African American) between the ages of 14.5 and 15.5 months

(M = 14.77). To obtain data from these 16 infants, it was necessary to test 24. The additional 8 participants were excluded for the following reasons: fussing or crying (7), experimental error (1). According to parental report, all children were free of ear infection at the time of testing, and reported no history of hearing problems. Children were recruited from the Pittsburgh area via mailing. The participants primarily came from middle- or upper-middle-class socioeconomic status (SES) families.

Stimuli

Participants were exposed to three novel objects, each paired with a unique label. The three objects were identical to those used by Stager and Werker (1997) and Thiessen (2007). Each object was animated and moved against a black background. Each of the three labels was produced by the SoftVoice computer synthesizer, set to a female voice, and a monotonic production with a fundamental frequency of 220 Hz.

The first object was paired with the label *yad* [jaed] or the label *yat* [jaet] (here and elsewhere, brackets indicate IPA transcription). Each infant heard only one of these labels—either *yad* or *yat*—during the habituation phase. The second object was paired with the label *dawbow* [dabo], and the third object was paired with the label *tawgoo* [tagu]. The labels *dawbow* and *tawgoo* were the identical synthesized recordings as those used in Thiessen (2007), and the labels *yad* and *yat* were synthesized to have matching pitch, amplitude, and vocal quality. Following Thiessen's original experiment, there was only a single token of each synthesized label used during the habituation and test phases. Each label was repeated for as long as the object remained on screen, with pauses of 1.4 s between repetitions.

Procedure

This experiment used a variant of the habituation procedure employed by Stager and Werker (1997) procedure, and identical to that used in Thiessen (2007). Participants, seated on a parent's lap in a sound-attenuated room, controlled the duration of the presentation of the stimuli by the length of their gaze at a central monitor. To eliminate bias, parents wore headphones, and the experimenters sat in an adjacent room, blind to the nature of the stimulus being presented. The experimenter coded the duration of the child's looking time online, using a Macintosh running the Habit program for OS X (Cohen, Atkison, & Chaput, 2004). After the child reached the habituation criterion (looking time less than 50% of the average of the first three trials), six test trials were presented.

The child controlled the duration of stimulus presentation, during both the habituation and test phases, by gazing at a 32′ video monitor 150 cm in front of their seated position. The child's attention was attracted to the monitor by a colorful video of Winnie the Pooh coupled with a recorded verbal encouragement. Once the experimenter determined the child's attention was fixated on the monitor, stimulus presentation was initiated. An object then appeared on the screen and the speakers adjacent to the monitor began to repeat the label associated with that object. The stimulus presentation continued until the child looked away for more than 1.5 s, or until the child had gazed at the monitor for 20 s (the maximum time allowed per trial). The video of Winnie the Pooh appeared at the end of each trial to recapture the child's attention.

The experiment began with two familiarization trials, in which participants saw a nonsense object paired with the word *neem* (a recording from a trained female speaker). The familiarization trials were used to help participants become accustomed to the pairing of audio and visual stimuli. Once these trials were finished, the habituation phase began.

During the habituation trials, one of the three novel objects appeared on screen, and was paired with a unique label (Object 1 was always paired with *yad* or *yat*; Object 2 was always paired with *dawbow*, and Object 3 was always paired with *tawgoo*). The objects were presented in blocks of three trials, and the order of presentation was random within those blocks. As in Thiessen (2007), each participant was required to complete at least two habituation blocks, or their data were excluded (all participants reached this threshold). Each object moved onscreen while the label was repeated with pauses of 1.4 s between each repetition. The object and the label were presented until the child looked away from the monitor for 1.5 s, at which point the attention-getting stimulus reappeared. Looking times to each trial were calculated in real time, and the habituation trials continued in random order until the child met the habituation criterion: Average looking time for three consecutive trials that fell below 50% of their looking time to the first three habituation trials.

Once the child met the habituation criterion, the six test trials began. In all test trials, the child saw Object 1 on the monitor. There were two kinds of test trials: same and switch trials. In the same trials, the children heard the syllable that they had previously heard paired with Object 1. For half of the infants, this was *yad*; for the other half of the infants, this was *yat*. In the switch trials, Object 1 was paired with a minimal pair of the label infants had heard in the habituation phase. For infants exposed to the object paired with *yad*, the switch trial paired the object with the novel label *yat*. The opposite was true for infants exposed to *yat* during the habituation phase.

Same and switch trials alternated, and the nature of the initial test trial was counterbalanced across participants. As in the habituation trials, the object stayed on the screen, and the label continued to repeat, for as long as the participant continued to look at the monitor.

Results and Discussion

On average, children habituated in 8.9 trials. Although children habituated in fewer trials to *yad* ($M = 7.5$) than to *yat* ($M = 10.2$) during the habituation phase, the difference was only marginally significant, $t(14) = 1.9$, $p = .08$, Cohen's $d = 0.55$. More importantly, children's preference for same versus switch test trials did not differ as a function of which item they heard during the habituation phase, $t(14) = 1.5$, $p = .15$, Cohen's $d = 0.41$. Therefore, for all subsequent analyses, participants were grouped together, regardless of which item they heard during the habituation phase. During the habituation phase, infants spent an average of 96.5 s ($SD = 28.6$) looking to the objects during the habituation phase. Thus, on average infants accumulated approximately 30 s of looking to the object labeled *yad/yat*.

Our primary question was whether infants in the test phase responded differentially to trials in which the novel object was paired with its original label (same trials), versus trials in which the object was paired with a minimal pair of that label (switch trials). As illustrated in Figure 1, children did not respond differentially to same and switch trials. A two-tailed t test (all t tests reported are two-tailed) indicated that the difference in looking times between same and switch trials was not significant, $t(15) < 1$, *ns*, Cohen's $d = 0.04$.

These results contrast sharply with those of Thiessen (2007). In that experiment, exposure to *dawbow* and *tawgoo* lead children to respond differentially to objects paired with *daw* versus *taw*. Here, after exposure to *dawbow* and *tawgoo*, children responded equivalently *yad* and *yat*. One possibility is that the sample size in this experiment was too small to yield a significant result; the sample size in Thiessen was 24 infants, compared to only 16 in this experiment. A power analysis indicated that for an effect the size in the Thiessen paper (approximated by a Cohen's d of .75, given the reported difference of 1.9 s between groups and a standard deviation of 2.4 s), the probability of identifying a significant result with the current sample size of 16 is only 54%. A sample size of 30 would yield a greater than 80% probability of finding an effect. Thus, in Experiment 2 we utilized a larger sample size. Another possibility is that children are unable to hear the difference between [d] and [t] in word-final position. However, the results of Experiment 3 (below) indicate that children can respond to this contrast in word-final position.

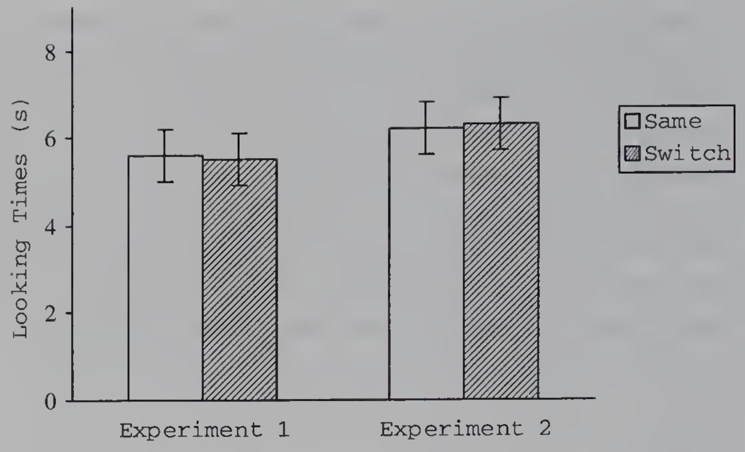

Figure 1. Children's looking time to same and switch trials after exposure to *Dawbow* and *Tawgoo*.
Note. In Experiment 1, same and switch trials are *yad* versus *yat*; in Experiment 2, they are *dee* versus *tee*. Error bars indicate ± standard error.

There is, though, a theoretical possibility consistent with the lack of a significant difference found in this experiment. What children learn from experiencing speech sounds in distinct lexical contexts (as with the [d] and [t] sounds in *dawbow* and *tawgoo*) does not lead, at least initially, to generalizations about abstract units such as features or phonemes. Instead, children may be learning about more specific, contextually bound units. That is, children's learning may be limited to situations that share a high degree of similarity to their initial experience. For example, exposure to *dawbow* and *tawgoo* may only facilitate use of [d] and [t] in word-initial position, or even be limited to a particular syllabic context. Whereas children fail to use the [d]–[t] contrast in word-final position, they may succeed if tested with contexts in which the [d]–[t] contrast is realized in a way that is more similar to its occurrence in *dawbow* and *tawgoo*.

Experiment 2

Writing and phonemic systems use the same symbols to indicate a phoneme in different word positions. However, the acoustic realization of phonemes differs in as a function of context. For example, the phoneme [t] is aspirated in *tear*, while it is unaspirated in *steer*. The [t] in *steer* sounds, when the preceding fricative is removed, much like a [d] (e.g., Maye, Werker, & Gerken, 2002). Similarly, phonemes are articulated quite differently in word-initial position than in word-final position, and these articulatory differences lead to differences in the acoustic realization of the phoneme (Stevens, 1998). If children are representing speech sounds in a nonabstract manner, the acoustic differences between word-initial and word-final position may make it difficult for children to generalize from information about a phonemic contrast across word positions; experience with *dawbow* and *tawgoo* may not be readily applicable to *yad* and *yat*.

However, testing generalization by presenting phonemes in word-final position may be especially challenging for young children. The ends of words appear to be less salient than word-onset positions for children (e.g., Clark, 1991), and word-initial information may be especially salient given its role in word recognition (e.g., Marslen-Wilson, 1987; Rodd, 2004). Given children's potential difficulty with word-final position, asking children to generalize from word-initial to word-final position may be an overly conservative test of generalization. In Experiment 2, we tested generalization from one word-initial setting to a second word-initial setting, in a different syllabic context. As in Experiment 1, children were exposed to three novel object–label pairings: objects labeled *dawbow*, *tawgoo*, and *dee*. According to Thiessen (2007), experience with *dawbow* and *tawgoo* facilitates children's use of the contrast between *daw* and *taw*. If children are learning about a relatively abstract contrast, they should also be facilitated in their use of the contrast between *dee* and *tee*.

Method

Participants

Participants were 30 toddlers (half female; 26 Caucasian and 4 Asian) between the ages of 14.5 and 15.5 months ($M = 15.22$). To obtain data from these 30 children, it was necessary to test 37. The additional 7 participants were excluded for the following reasons: fussing or crying (5), experimental error (2). According to parental report, all children were free of ear infection at the time of testing, and reported no history of hearing problems. Children were recruited from the Pittsburgh area via mailing. The participants primarily came from middle- or upper-middle-class SES families.

Stimuli

The computer-animated objects were identical to those used in Experiment 1, as were the words *dawbow* and *tawgoo*. The only difference between the stimuli used in Experiment 1, and the stimuli used in this experiment, was that Object 1 was paired with the labels *dee* [di] or *tee* [ti] (each infant heard only one during the habituation phase). These labels replaced *yad* and *yat* from Experiment 1, and were synthesized using the same acoustic parameters as the stimuli in that experiment. As in Experiment 1, there was only a single repeated token of each label.

Procedure

The procedure was identical to that of Experiment 1. After the habituation phase, infants were presented with same and switch trials. On same trials, Object 1 was paired with the same label as it was during the habituation phase. On switch trials, it was paired with a minimal pair of that label. Thus, for infants who heard *dee* during the habituation phase, the switch trial presented the word *tee*.

Results and Discussion

On average, children exposed to *dee* (in addition to *dawbow* and *tawgoo*) habituated in 13.4 trials, while children exposed to *tee* (in addition to *dawbow* and *tawgoo*) habituated in 6.9 trials. This difference was significant, $t(28) = 2.7$, $p < .05$, Cohen's $d = 1.02$. Infants exposed to *dee* spent an average of 128.1 s ($SD = 75.4$) looking to the objects during the habituation phase. Infants exposed to *tee* spent an average of 79.4 s ($SD = 35.4$) looking to the objects during the habituation phase. This difference was also significant, $t(28) = 2.3$, $p < .05$, Cohen's $d = 0.83$. It is unclear why children found one set of habituation trials more interesting than the other. It may be indicative of a preference for the speech synthesizer's production of voiced items over voiceless items, or a difference in children's familiarity with these particular syllables in their natural environment. However, any possible item preference did not influence children's performance on the test items: There was no significant difference in children's preference for same versus switch trials as a function of their exposure to *dee* or *tee*, $t(28) < 1$, *ns*, Cohen's $d = 0.06$.

Given that the differences in rate of habituation suggested that children may have performed differently as a function of exposure, we analyzed the group data separately, using a 2 (habituation: *dee* or *tee*) × 2 (test trial: same vs. switch) analysis of variance (ANOVA). There was no main effect of habituation, $F(1, 28) < 1$, *n.s.*, $\eta_p^2 = .01$. Nor was there any interaction between habituation and test item, $F(1, 28) < 1$, *ns*, $\eta_p^2 = .01$.

Most importantly, there was no difference in children's looking time to same or switch trials $F(1, 28) < 1$, *n.s.*, $\eta_p^2 = .01$. Figure 1 illustrates the average looking time to same and switch trials, averaged across both groups of infants (habituated to *dee*, or habituated to *tee*).

These results suggest that exposure to *dawbow* and *tawgoo* had little, if any, effect on children's use of the [d] and [t] contrast in a novel syllabic context. Whereas *dawbow* and *tawgoo* facilitated children's use of the contrast in the same (*daw–taw*) syllabic context (Thiessen, 2007), children continued to treat minimal pair words differentiated by the contrast interchangeably, when the contrast was embedded in a novel syllable. This indicates that what children may not readily generalize at the level of abstract phonemes, or context-free features. Instead, children's learning appears to be strongly tied to specific, previously experienced, contexts.

Experiment 3

The results of Experiment 1 and 2, taken together, suggest that children are not generalizing at the level of abstract units such as phonemes or features. Rather, their use of speech sounds to indicate contrasts in meaning appears to be contextually bound. If so, then it should be easiest to facilitate children's use of a phonemic contrast in a particular context by providing them distributional evidence about that phoneme in an identical context. To test this hypothesis, children in Experiment 3 were tested using the *yad–yat* pairing from Experiment 1. However, children received distributional information about the [d]–[t] contrast in word-final position (the words *boeyad* vs. *gooyat*). This experience with the contrast in word-final position should facilitate its use in *yad–yat*, unlike the experience with the phonemes in word-initial position in Experiment 1.

To increase the ecological validity of the comparison between word-initial and word-final position, Experiment 3 used natural speech, as opposed to synthesized speech; this necessitated a replication of the data from Experiment 1 with the new, natural stimuli. As such, there were three conditions in this experiment.

Single Object

In this condition, children were habituated to a single object, paired with the label *yad*. Following the results of Stager and Werker (1997), children should fail to respond differentially to same (*yad*) and switch (*yat*) trials.

Word Initial

This condition replicates Experiment 1. In addition to *yad*, children were habituated to two objects labeled *dawbow* and *tawgoo*, providing information about the distribution of [d] and [t] in word-initial condition. If the results of natural speech parallel the results with synthesized speech, children should also fail to respond differentially to same and switch trials.

Word Final

In this condition, children were habituated to objects labeled *yad*, *boeyad* [bojaed], and *gooyat* [gujaet]. This condition provides evidence that the [d]–[t] contrast occurs in different distributions in word-final position, and thus should be the condition in which children are most successful at responding differentially to the contrast in word-final position.

Method

Participants

Participants were 60 toddlers (half female; 51 Caucasian, 4 Asian, 4 African American, and 1 Hispanic) between the ages of 15.0 and 16.5 months ($M = 15.4$). Twenty were assigned to the single-object condition, 20 were assigned to the word-initial condition, and 20 were assigned to the word-final condition. To obtain data from these 60 participants, it was necessary to test 73. The additional 13 infants were excluded for the following reasons: fussing or crying (8), experimental error (2), parental interference (2), and looking times averaging < 2 s during test trials (1). According to parental report, all children were free of ear infection at the time of testing, and reported no history of hearing problems. Children were recruited from the Pittsburgh area via mailing. The participants primarily came from middle- or upper-middle-class SES families.

Stimuli

The computer-animated objects were identical to those used in Experiment 1. However, the audio stimuli were recorded from utterances produced by a female native speaker of English, and digitally edited to match the amplitude of the stimuli used in Experiments 1 and 2. The test items (*yad* and *yat*) were produced by the same speaker. As in prior experiments, only a single token of each label was used during the habituation and test phases.

Procedure

All participants saw Object 1 paired with the nonsense word *yad*. In the single-object condition, this was the only word–object pairing to which children were habituated. In the word-initial condition, children saw two additional objects, labeled *dawbow* and *tawgoo*. This replicates Experiment 1, providing distributional information about the [d]–[t] contrast in word-initial position.

The third condition was the word-final condition, in which children were provided with distributional information about the [d]–[t] contrast in word-final position. In this condition, children were habituated to Object 1 paired with *yad*, and two additional objects paired with *boeyad* and *gooyat*.

The habituation procedure used was identical to that of Experiment 1 and 2. After habituation, all infants were tested on same and switch trials, as in Experiment 1. On same trials, Object 1 was paired with the familiar label *yad;* on switch trials, it was paired with the novel label *yat*.

Results and Discussion

Participants in the single-word condition habituated in fewer trials ($M = 6.8$) than participants in either the word-initial ($M = 10.2$) or word-final condition ($M = 9.8$). Similarly, participants in the single-word condition spent less overall time looking during the habituation phase ($M = 58.3$ s, $SD = 28.5$) than infants in either the word-initial ($M = 112.1$ s, $SD = 47.6$) or word-final condition (104.6, $SD = 39.1$). This is unsurprising, as participants in the word-initial and word-final conditions were exposed to three word-object pairings during the habituation phase, whereas participants in the single-object condition were only exposed to one. These results mimic those of Thiessen (2007), where children habituated more quickly to a single object than multiple objects.

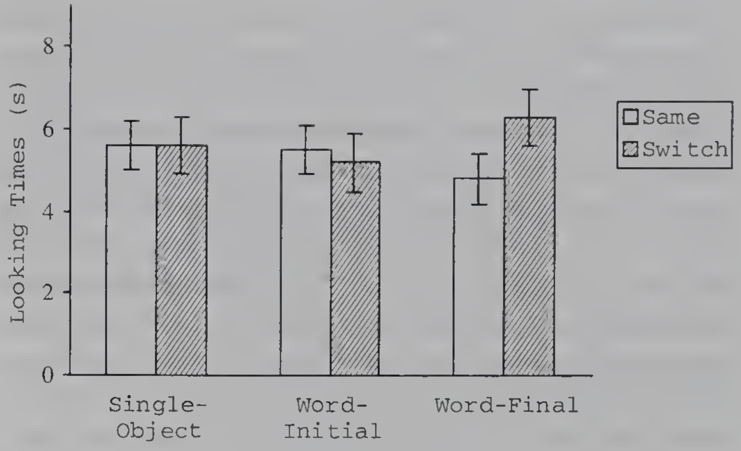

Figure 2. Children's looking time to same and switch trials in the three conditions of Experiment 3.
Note. The difference between same and switch trials was significant only in the word-final condition. Error bars indicate ± standard error.

As seen in Figure 2, participants in the single-object condition responded equivalently to same and switch trials, $t(19) < 1$, *ns*, Cohen's $d = 0.01$. Children's lack of differentiation between object labels differing by only a single phoneme replicates Stager and Werker's (1997) original experiment, and many other demonstrations that children at this age have difficulty responding to single-phoneme differences in word–object association tasks (e.g., Pater et al., 2004; Shvachkin, 1948/1973; Werker et al., 2002).

In the word-initial condition (in which infants were exposed to *dawbow* and *tawgoo*, in addition to *yad*), children also failed to respond differentially to same and switch trials, $t(19) < 1$, *ns*, Cohen's $d = 0.14$. Children's looking times to same and switch trials are illustrated in Figure 2; their failure to respond differentially to the test trials replicates Experiment 1.

Most importantly, as seen in Figure 2, children in the word-final condition responded differentially to same and switch trials. This difference was significant, $t(19) = 2.4$, $p < .05$, Cohen's $d = 0.6$. Unlike experience with *dawbow* and *tawgoo* (the word-initial condition), exposure to *boeyad* and *gooyat* facilitated children's response to the difference between *yad* and *yat*.

To more thoroughly explore the difference between the word-initial and word-final condition, we performed a 2 (condition) × 2 (test trial type) ANOVA. There was no main effect of condition, $F(1, 38) < 1$, *ns*, $\eta_p^2 = .01$. This suggests that looking times were equivalent across the two conditions. There was also no main effect of test item, $F(1, 38) = 1.2$, $p = .27$, $\eta_p^2 = .03$. This lack of effect is not surprising, as participants did not demonstrate a consistent preference for items across conditions. Most importantly, however, there was an interaction between condition and item, $F(1, 38) = 5.1$, $p < .05$, $\eta_p^2 = .12$. This interaction indicates that toddlers' preference in the word-final condition significantly differs from their lack of preference in the word-initial prediction. These results support the hypothesis that children's performance is better when they receive distributional information in the same context as the phonemes are presented in the test trials.

The difference between the word-initial and word-final conditions is informative about the nature of children's early generalization of speech sounds. In both conditions, children received distributional evidence that the phonemes [d] and [t] occur in different lexical forms; this kind of distributional evidence has previously been found to facilitate children's use of phonemic contrasts (Thiessen, 2007). However, only distributional information in the same syllable and word position facilitated children's ability to use the contrast at test. Children in the word-initial condition, who received distributional information about the phonemes in different syllables and word positions, performed like children in the single-object condition who received no distributional information at all. This suggests that children's generalization is limited, at least initially, to contexts that are highly similar to their prior experience.

One potential confound needs to be addressed: There is a possibility that children respond differently in the two conditions, not because of the context of the distributional information they received but because they receive different amounts of exposure to the stimuli. Morgan, Duran, and Layton (2005) have suggested that the ability to dishabituate in experiments of this type is mediated by amount of exposure; when children are overexposed to a particular sound, they become less sensitive to it. Alternatively, children may have received less exposure to the *yad*-object in the word-initial condition and thus not learned the pairings between sound and object. To assess these possibilities, we performed a two-tailed t test comparing length of exposure during the habituation phase for children in the word-initial condition ($M = 112.1$ s, $SD = 47.6$) and children in the word-final condition (104.6, $SD = 39.1$). There was no significant difference, $t(38) < 1$, *ns*, Cohen's $d = 0.17$. This suggests that length of exposure does not explain why children differentiate between same and switch trials in the word-final condition, and fail to do so in the word-initial condition. Instead, this analysis reinforces the hypothesis that the critical difference in these conditions relates to the similarity between the distributional information children receive during testing and the context in which phonemic distinctions occur during test trials.

As such, these results are inconsistent with accounts in which children's early representations of speech are organized in such a way as to allow automatic generalization at the level of abstract phonemes. If phonemic representations were entirely abstract (e.g., bundles of features), children's use of those phonemes should generalize widely (e.g., Berent et al., 2002; Lindblom et al., 2008; Shvachkin, 1948/1973). Instead, the current results suggest that children are storing some amount of contextual (i.e., not abstracted) detail about their prior experience with phonemes. This detail may be related to word position, syllabic context, or some other acoustic aspect of the specific realization of the previously experienced phoneme. These details persist and lead to performance that is better when the context matches training than when it does not. While the precise nature of children's representation is still ambiguous (see the General Discussion), the fact that children perform better in the word-final condition than in the word-initial condition indicates that children's representations of early word forms are rich with contextual detail.

General Discussion

To master their native language, children must learn which sound contrasts indicate a difference in meaning and which do not. While children make remarkable progress in that regard during their 1st year of life (e.g., Werker & Tees, 1984), they still have some difficulty using these distinctions in a word–object association task into the 2nd year (e.g., Stager & Werker, 1997). By 17 months, children are more successful at making use of at least some of these single phoneme differences (Werker et al., 2002), although they may not be proficient with every contrast present in their native language until later (Shvachkin, 1948/1973). While a number of explanations have been proposed for this developmental difference—including increases in capacity (Stager & Werker, 1997) and understanding of referential intent (e.g., Fennell, 2008)—the current results provide support for accounts suggesting that older children are successful because they have more information about the distribution of phonemes in their native language (e.g., Thiessen, 2007).

Children's vocabularies grow dramatically during the 2nd year of life (e.g., Fenson et al., 2002). During this time, most of the words children learn provide evidence of phonemes occurring in different lexical contexts (like /b/ and [d] in *baby* and *diaper*). Young children know comparatively few words in which two different phonemes occur in identical contexts (minimal pair words like *ball* and *doll*), far fewer, both absolutely and as a relative proportion of their vocabulary, than adults (e.g., Coady & Aslin, 2003). As demonstrated by Experiment 3, and also by Thiessen (2007), experiencing phonemes in different lexical contexts helps children to use the phonemic distinction in word–object association tasks. Further, children with larger vocabularies, and thus more evidence that phonemes are distributed in different words, are more successful using phonemic distinctions in word–object association tasks (Werker et al., 2002). These results converge to suggest that vocabulary growth plays an important role in children's use of phonemic contrasts by providing children with distributional information.

The current results are novel in that they indicate that children's generalization of the distributional information they receive is somewhat limited. Children are more likely to take advantage of distributional information about a phonemic contrast when that contrast is tested in the same context as the original distributional information. While these results do not rule out the possibility that some aspects of children's representation of word forms are abstract (e.g., featural), they indicate that children must be storing some contextual detail about their prior experience with phonemes. This is inconsistent with theories that argue that representation of speech is primarily or completely abstract. For example, most featural theories of representation argue that phonemes can be reduced to bundles of abstract features that are invariant across word position or syllabic context (e.g., Chomsky & Halle, 1968; Cole & Scott, 1974; Eulitz & Lahiri, 2004). It is a common assumption that children's representations of speech can be characterized by the same kinds of abstract representations (e.g., Dinnsen et al., 2001). The context specificity of the current results is inconsistent with abstract representations like features or phonemes, although it may be the case that abstract representations and contextual acoustic detail are processed separately and in parallel (e.g., Hanson, 1977; Remez et al., 1997). One possibility is that abstract representations, such as phonemes, can incorporate contextual detail such as the syllabic context in which the phoneme occurred in ways that limit the generalizations learners make about those phonemes in other contexts (e.g., Prince & Tesar, 2004).

Indeed, these results, and others like them (e.g., Houston & Jusczyk, 2003) are consistent with accounts positing that representations of speech are not composed of abstract, phonologically pure components (e.g., Goldinger, 1996). While phonemes and features are useful descriptively, the evidence for the psychological reality of phonemes has been criticized on a number of grounds (e.g., Lotto & Holt, 2003). Many phenomena once thought to be decisive evidence in favor of abstract representations, such as context effects, have now been demonstrated to occur in the absence of phonemic knowledge (e.g., Lotto, Kluender, & Holt, 1997; Mann, 1986). Similarly, intraphonemic variation, which should be discarded on abstract representational accounts, clearly plays a role in adult speech perception (e.g., Volaitis & Miller, 1992). Although both adults and infants appear to respond to phonological categories in ways that are consistent with abstract representations (e.g., Eimas et al., 1971), it may be the case that nonabstract systems could accomplish the same feats (Bybee & McClelland, 2005). For example, when infants generalize on the basis of a feature such as voicing (e.g., Maye et al., 2008), this generalization may be due to acoustic similarities among voiced consonants, rather than a commonality in the abstract featural representation + voicing. However, caution is due in interpreting the current results; evidence that children's representations are not completely abstract is not logically sufficient to rule out some degree of abstraction.

Some authors have suggested that the degree of abstraction in children's representation varies by the task in which they are engaged, or their developmental state (e.g., Shvachkin, 1948/1973). Child phonologists have proposed a discontinuity between the types of representations used in perceptual tasks (such as speech discrimination) and the representations used for word learning and language more broadly (e.g., Barton, 1980; Brown & Matthews, 1997; Ferguson & Farwell, 1979). One possibility that this raises is that children's representations in the current tasks looked relatively concrete because they were not treating the task as truly linguistic, but rather as a perceptual association task. On this kind of account, had the training been embedded in a more naturalistic setting, children may have engaged a different set of representations and generalized their phonemic usage more widely. By contrast, Werker et al. (2002) have proposed that the underlying representations used by infants in both perceptual and linguistic tasks are identical. Due to the fact that word-learning and perceptual tasks typically differ in their difficulty (word-learning tasks are more difficult because they require forming an association between words and objects), children show differing degrees of sensitivity to phonemic variation in the two kinds of tasks. While the current data do not differentiate between these two accounts, other work indicates that lessening the difficulty of word-learning tasks—whether by using familiar objects (e.g., Fennell, 2006), or prefamiliarized labels (e.g., Swingley, 2007)—leads infants to perform more successfully in word–object association tasks. This pattern of results is more consistent with theories positing a continuous representational system than theories positing discontinuous representational systems.

This should not be taken as evidence that there are no developmental differences in children's representations over time. A number of theorists have argued that more abstract representations emerge over time (e.g., Best, Tyler, Gooding, Orlando, & Quann, 2009; Dietrich et al., 2007). Werker and Curtin (2005), for example, have proposed that children's representational system encodes subphonemic and indexical information throughout the course of development. As children gain more experience with their native language, they come to attend more to phonemic aspects of these representations than to more idiosyncratic factors. This may explain why older children are more successful in using phonemic detail in word–object association tasks (e.g., Werker et al., 2002). The emergence of less context-specific phonemic distinctions may occur as a function of children's experience with these contrasts in more varied contexts (e.g., Rost & MacMurray, 2009). In these experiments, children failed to generalize a phonemic contrast after experiencing it in a single vocalic or syllabic context. However, generalization may be possible after experiencing the contrast in multiple contexts, as suggested by models of generalization in memory (e.g., Hintzman, 1986). As a contrast is experienced in multiple different contexts, the information that is consistent—the contrast itself—is emphasized, while the variable contextual information is less supported in memory. The emergence of behavior governed by (seemingly) abstract units from contextually detailed representations is consistent with a variety of formal models.

However, before the predictions of such models can be fully evaluated, it is critical to understand the nature of the contextual detail encoded in children's representations. While the current results demonstrate that children's representations of speech incorporate some kind of contextual detail about their prior experience with phonemes, the nature of that contextual information is still uncertain. Two (potentially complementary) possibilities have been suggested in prior theories of linguistic development: context at a grain size above the phoneme, such as syllables, and more granular acoustic context, such as coarticulatory information. The syllable is a universal feature of human linguistic systems; additionally, syllables are both perceptually salient and relatively limited in number. Infants appear to be sensitive to the presence and identity of syllables in speech (e.g., Bertoncini, Bijeljic-Babic, Jusczyk, Kennedy, & Mehler, 1988; Jusczyk & Derrah, 1987). Because of these facts, a number of theorists have argued that syllables may play an important role in children's early representations of speech (e.g., Mehler, Dupoux, & Segui, 1990). On these kinds of accounts, the syllable is an undifferentiated unit, not composed of combinatorially distinct subcomponents. This lack of subcomponents (phonemes or features) renders a syllabic account consistent with the current results. When children are exposed to *dawbow* and *tawgoo*, they are learning about the syllables *daw* and *taw*, not the phonemes [d] and [t] or the features [−voice] and [+voice]. Therefore, there is little reason to expect generalization to syllable contrasts like *yad/yat* or *dee/tee*. This syllable-level account is consistent with theories of phonotactic learning in which generalization is conditioned upon the syllabic context in which a particular phoneme has been previously encountered (e.g., Prince & Tesar, 2004).

An alternative, although not mutually exclusive, possibility is that different instances of particular phonemes might be differentiated by fine-grained acoustic differences in the realization of the phoneme itself. Both infants and adults are sensitive to intraphonemic differences: differences in the articulation of two exemplars of the same phonemic category (e.g., McMurray & Aslin, 2005; Volaitis &

Miller, 1992). Representation of these intraphonemic differences is often assumed in exemplar memory models of speech representation (e.g., Goldinger, 1998). Similarly, the WRAPSA model of speech perception (Jusczyk, 1993, 1997) proposes that the developmentally earliest form of representation is a spectral and temporal code derived immediately from the acoustic signal itself. The fact that infants recognize words more easily after a delay when they are spoken by the same speaker than when they are produced by a novel speaker (Houston & Jusczyk, 2003; Singh, 2008) is consistent with approaches emphasizing a fine-grained acoustic basis of representation, because it indicates that infants' representation of the word forms preserves idiosyncratic acoustic indexical information such as rate of speech. If young children are representing intraphonemic acoustic details, generalization should also be more limited than is the case with an abstract phonological system. This is because different speech sounds are realized quite differently in different contexts, due to coarticulatory processes. The realization of [d] in *yad* is quite different than the realization in *dawbow*. By contrast, the [d] in *boeyad* is nearly identical to the [d] in *yad*, making distributional information from *boeyad* much easier to apply to *yad* than distributional information from *dawbow*.

Subsequent experimentation will be necessary to assess the precise nature of the contextual detail present in young children's representations of word forms. The current results demonstrate that children fail to generalize to a segment that shares a feature (like voicing) in a very different syllabic position, or followed by a very different vowel. But children might be successful if they were tested on the same feature—in the same syllabic and vocalic context—at a different place of articulation. For example, children might successfully use the distinction between *baw* and *paw* after exposure to *dawbow* and *tawgoo* (we thank an anonymous reviewer for this suggestion). Alternatively, children may generalize to a different syllable as long as the vocalic context and syllabic position are the same. That is, after exposure to *dawbow* and *tawgoo*, children may use the distinction between *dock* and *talk*. If children are representing intraphonemic acoustic variation, they should be successful in this training scenario (a variant of which we are currently running in our lab), since the phonemes [d] and [t] are articulated in the same way in *dawbow* and *dock* and *tawgoo* and *talk*, occurring in the same syllabic position and vocalic context. By contrast, if children are representing syllabically, they may fail in this training regime, since *dock* and *talk* are novel syllables.

The current results do not distinguish between a syllabic and coarticulatory account of the contextual information stored in young children's representations of early word forms (for a discussion, see Jusczyk, 1993; Coady & Aslin, 2004). But on either account, consistent with the current results, children's representations are not characterized solely by abstract phonemic or featural components. This leads to a different view of the developmental processes between the age when children fail to use phonemic differences in word-learning tasks (Stager & Werker, 1997), and the age when they succeed (Werker et al., 2002). If children are representing words using featural or phonemic representations, the change between failure and success is somewhat mysterious, as children are already using appropriate units. One way to resolve this dilemma is to propose that children's early representations of speech are holistic and underspecified (e.g., Walley, 1993). For example, a word like *dog* might, early in lexical development, be represented only by the single feature +alveolar. However, recent research on comprehension is largely inconsistent with an underspecification account (although see Kager, Van der Feest, Fikkert, Kerkhoff, and Zamuner, 2007, for production data consistent with underspecification). Young children are highly sensitive to even slight mispronunciations of known words (e.g., Swingley & Aslin, 2000, 2002, 2007), and even some novel words (Mani & Plunkett, 2008).

Rather than underspecification, these results suggest that young children's early word learning may fail to take advantage of phonemic differences due to the richness of the input and children's representations (cf. Werker & Curtin, 2005). There are a multitude of acoustic differences to which children are sensitive (e.g., Houston & Jusczyk, 2003; McMurray & Aslin, 2005). Some of these acoustic differences indicate differences in meaning, but many do not. Children may need to receive information from their linguistic environment about which of these differences are informative in word-learning tasks before they begin to use them productively. For example, hearing examples of two different phonemes distributed in different word forms helps children subsequently use that phonemic contrast when using novel words (Thiessen, 2007). The current results are consistent with accounts suggesting that children's representations are rich and multidimensional, insofar as they indicate children's representations are not entirely abstracted but instead incorporate contextual detail. To the extent that children's representations incorporate variability, children may need to receive evidence about which facets of that variability are productive in particular tasks.

This kind of contextual sensitivity, coupled with a learning account, leads to novel predictions about the developmental time course of children's use of different phonemic contrasts. Abstract representational accounts assert that the development in children's use of phonemic contrasts should be sudden (e.g., Lindblom et al., 2008; Nazzi & Bertoncini, 2003); once a child has learned to use a featural contrast (e.g., voicing) in one situation, that contrast can be widely used. By contrast, the current results indicate limited generalization and predict a more graded development in children's use of phonemic contrasts in word learning. More common contrasts should begin to be used earlier than less common contrasts. Similarly, a sound that occurs disproportionately often in word-initial position should be productive in that position earlier than it is productive in other word positions (cf. Schafer & Mareschal, 2001). While there is currently little data to assess these predictions (although see Shvachkin, 1948/1973; Thiessen & Yee, 2008), the current results provide an empirical demonstration that children's use of a phonemic contrast in one context does not immediately generalize to other contexts.

Note, however, that the present findings indicating conservative generalization do not mean that young learners are incapable of generalizing their experience with speech sounds. In particular, prior research suggests that variability in the input facilitates generalization (e.g., Gomez, 2002; Lively, Logan, & Pisoni, 1993). Maye et al. (2008) found that infants who learned to discriminate a featural contrast were able to generalize that learning to a novel contrast varying on the same feature; in that experiment, infants were exposed to multiple exemplars of the featural contrast. Participants in these experiments received only a single exemplar of each to-be-learned label. Young children may well be able to generalize in word–object association tasks if they receive training that more robustly supports generalization beyond specific contexts, such as experiencing a phonemic contrast (e.g., [d]–[t]) in multiple syllabic contexts. This would be consistent with both prior work (e.g., Maye et al., 2002; Rost & MacMurray, 2009) and the current experiments, indicating that infants are sensitive to the distribution of acoustic details in the input and that this distribution plays an important role in the development of children's linguistic abilities.

An Eye for Detail: An Event-Related Potential Study of the Rapid Processing of Fearful Facial Expressions in Children

Petra H. J. M. Vlamings and
Lisa M. Jonkman
Maastricht University

Chantal Kemner

Medical Center Utrecht*

There is converging evidence for the presence of a fast subcortical face-processing route that operates on global face characteristics in the mature brain. Until now, little has been known about the development of such a route, which is surprising given suggestions that this fast subcortical face-processing route might be affected in neurodevelopmental disorders such as autism. To address this, early visual event-related potentials to pictures of fearful and neutral faces containing detailed or global information in 3- to 4-year-old ($n = 20$), 5- to 6-year-old ($n = 25$), and 7- to 8-year-old ($n = 25$) children were compared. In children, emotional processing was driven by detailed information. Developmental effects are discussed in terms of maturation of the fast subcortical face-processing route as well as an increase in experience with facial expressions with age.

Decoding the emotional content of a face is an important skill in daily life because it helps to evaluate the state and the intentions of others. Given that facial expressions like fear, anger, or threat may be signals of potential danger, it is plausible that the detection and processing of emotional expression proceeds very fast. Several authors have investigated what information the visual system extracts to decode emotional expressions so rapidly (Holmes, Winston, & Eimer, 2005; Pourtois, Dan, Grandjean, Sander, & Vuilleumier, 2005; Vuilleumier, Armony, Driver, & Dolan, 2003; Winston, Vuilleumier, & Dolan, 2003). Visual information that enters our visual system consists of luminance variations, which occur in a wide range of so-called spatial frequencies and can be expressed in cycles per degree (cpd) of visual angle (e.g., De Valois & De Valois, 1988; Goldstein, 1999). Lower spatial frequencies (LSF) represent the large-scale variations, that is, coarse visual information such as shading or large contours, as well as the global configuration of the face (e.g., distance between eyes, eyebrows and mouth). High spatial frequencies (HSF) represent tighter gradients of luminance changes, that is, fine visual information (sharp edges, contours of features such as the mouth, eyes, wrinkles, and so on; Goffaux & Rossion, 2006; Morrison & Schyns, 2001).

By varying the spatial frequency content of a stimulus or image (by filtering out either high or low frequency information), one can study the difference in processing of this information (e.g., De Valois & De Valois, 1988; Goldstein, 1999).

Behavioral studies have provided evidence for differential sensitivity to HSF and LSF content of emotional expressions for face recognition or identification in adults. For instance, it has been shown that participants use LSF information to categorize rapidly emotional expressions, whereas HSF information seems to be most important for the success with which one can explicitly rate emotional expressiveness (or intensity), a process that may proceed at a slower time-scale (Schyns & Oliva, 1999; Vuilleumier et al., 2003; Deruelle & Fagot, 2005; however, see Goren and Wilson, 2006, for different effects using synthetic faces). In addition, the LSF components of faces are critical to the production of rapid behavioral or attentional responses toward fearful facial expressions (Holmes, Green, & Vuilleumier, 2005).

The authors gratefully thank Sabine Koenraads, Pia Jansen, Anne Hermans, and Eveline Eerdekens for helping with the data collection.

Several authors have hypothesized that the rapid processing of fear occurs through a subcortical route in the brain that rapidly processes fear based on LSF information (Pourtois et al., 2005; Vuilleumier et al., 2003; Winston et al., 2003). This route starts at the ganglion cells in the retina. There are two cell types in the retina that are differentially sensitive to HSF and LSF, respectively: parvocellular (small receptive fields) and magnocellular neurons (large receptive fields). Several studies have indicated that although parvocellular and magnocellular neurons respond to an overlapping range of SFs, parvocellular neurons are preferentially tuned (most active) to HSF, whereas magnocellular neurons are more sensitive to LSF information (Enroth-Cugell & Robson, 1966). Because the conduction velocity of axons of the parvocellular system is lower compared to the magnocellular system (see Hess, 2004), signals from the parvocellular system are transmitted more slowly compared to the magnocellular system (see for review Skottun & Skoyles, 2007). The amygdala, a key structure for emotion processing, receives direct input from subcortical regions (tectum and pulvinar) that primarily receive retinal magnocellular input (Pourtois et al., 2005; Vuilleumier et al., 2003; Winston et al., 2003). It has been proposed that this type of subcortical input would enable the amygdala to rapidly process facial expressions based on LSF and to provide quick signals about for example fear-related stimuli (Johnson, 2005; Pourtois et al., 2005; Vuilleumier et al., 2003; Winston et al., 2003).

Two functional magnetic resonance imaging (fMRI) studies indeed provided evidence for this and found that the amygdala and connected subcortical regions are primarily sensitive to low spatial frequency information: Enhanced activity to emotional expressions in the amygdala and other subcortical structures was found only for faces containing LSF, but not HSF, information (Vuilleumier et al., 2003; Winston et al., 2003). Similar effects were found in the fusiform gyrus, a cortical structure specifically involved in the visual processing of faces (Vuilleumier et al., 2003; Winston et al., 2003). Furthermore, two event-related brain potential (ERP) studies in adults found that rapid effects of emotion in visual regions were primarily mediated by LSF information (Pourtois et al., 2005; Vlamings, Goffaux, & Kemner, 2009). Based on these findings, a rapid, subcortical route (tecto-pulvinar-amygdala pathway) for facial expression processing has been proposed that operates on LSF information and modulates activity in visual cortical areas in which emotional signals are further processed (e.g., Le Doux, 1996; Vuilleumier et al., 2003; see for review Johnson, 2005). This fast subcortical face-processing route is seen as a "quick and dirty" route that extracts emotion based on global face characteristics or low spatial frequencies but not detailed information or HSF, which are processed through the "slower cortical route" (Johnson, 2005; Pourtois et al., 2005; Vuilleumier et al., 2003; Winston et al., 2003). Although the above-mentioned studies solely tested the role of SF in fear-related processing, this does not exclude the possibility that other types of facial expressions (e.g., threat-related) might also be processed by this subcortical face-processing route making use of LSF information. In addition, it is not known to what extent this (LSF) route distinguishes between different facial expressions (e.g., fear and surprise).

In sum, behavioral as well as neuroscientific studies in adults have provided evidence that the rapid processing of facial expressions is primarily driven by LSF information and that this might be driven by a rapid subcortical face-processing route that is preferentially tuned to LSF information. This quick and dirty route is thought to bypass the slower cortical route and is thought to modulate directly activity of specialized cortical areas in response to faces.

Little is known about the role of LSF and HSF in the perception of facial expressions in children. As described previously, there is converging evidence from studies in adults for a subcortical face-processing route that is rapid, operates on LSFs, and modulates cortical processing. The development of this pathway has not been studied, but Johnson (2005) suggested that newborn face processing and face preferences might primarily rely on this subcortical route or a precursor of it. This suggestion is based on evidence that face processing in newborns is primarily driven by subcortical pathways or brain structures as the visual and other cortical areas are still relatively immature.

In addition, the infant's limited visual capacities play a role in face processing in the 1st year of life. The vision of a newborn is solely based on LSF information (Acerra, Burnod, & de Schonen, 2002; Morison & Slater, 1985; Slater & Sykes, 1977). This is caused by immaturity of the visual system at several levels, such as lower photoreceptor density and shorter segment length at the retina level, relatively less developed parvocellular neurons (compared to magno-) at the lateral geniculate nucleus level and lower synaptic density and larger cortical receptive field size in the visual cortex (for reviews, see Ellemberg, Lewis, Liu, & Maurer, 1999; Hammarrenger et al., 2003). In agreement with this, a recent study by de Heering et al. (2008) found that face recognition in newborns is primarily steered by very low SF (< 0.5 cpd) information.

However, during infancy and early childhood, the visual system develops and other cortical areas also mature. Vision rapidly increases and, by the age of 3–4 years, sensitivity to HSF as measured by the contrast sensitivity function reaches maturity (e.g., Adams & Courage, 2002). The contrast sensitivity function measures the amount of contrast that is needed to detect a stimulus with a certain SF. Until now, no studies have addressed whether the type of information, HSF or LSF, that is important for rapid facial expression processing changes during development as children become able to perceive a larger range of spatial frequencies.

There is only one behavioral study (Deruelle & Fagot, 2005) that reported that 5- to 8-year-old children, *like adults* (Schyns & Oliva, 1999; Vuilleumier et al., 2003), rely on HSF information when explicitly processing emotional expressions from faces (deciding whether a face is smiling or not). There is, however, no information on whether the *rapid* processing of facial expressions in children is, as in adults, based on LSF information.

A better understanding of normal development of facial expression processing is important as facial expressions play an important role in the social-emotional development of children. In this study, we investigate the role of SF in facial expression processing in children 3–8 years old using ERPs. We primarily investigate the early stages of face processing in the visual areas of the brain, where interactions between SF and emotion have been found to occur in previous studies (Pourtois et al., 2005; Vlamings et al., 2009). Two visual peaks were studied: P1 and N170. The P1 is a positivity peak that occurs 100 ms after stimulus onset (SO). It is a fast exogenous response that reflects striate as well as extrastriate visual processing (e.g., Rossion et al., 1999). The N170 (negativity at 170 ms after SO) originates from a network of regions, probably including the fusiform gyrus, inferior occipital cortex, superior temporal sulcus and the inferior, middle and superior temporal gyri (Henson et al., 2003). The N170 is the earliest "face-specific" ERP component as its amplitude has been found to be consistently enhanced in response to faces in comparison to multiple other nonface, object categories (see for review Jacques & Rossion, 2004). A larger or faster P1 has been found for fearful compared to neutral expressions in adults (Eimer & Holmes, 2002; Pourtois, Grandjean, Sander, & Vuilleumier, 2004; Pourtois et al., 2005; Williams et al., 2004) as well as in infants (starting from 7 months of age) and children (Batty & Taylor, 2006; Dawson, Webb, Carver, Panagiotides, & McPartland, 2004; Nelson & de Haan, 1996). Other studies report effects of emotional expressions on the N170 peak. Typically, larger N170 amplitudes are seen in response to (negative) emotional expressions than to neutral or positive expressions in adults (Batty & Taylor, 2003, 2006; Blau, Maurer, Tottenham, & McCandliss, 2007; Campanella, Quinet, Bruyer, Crommelinck, & Guerit, 2002; Dawson et al., 2004; de Haan, Nelson, Gunnar, & Tout, 1998; Stekelenburg & de Gelder, 2004). In children, effects of (negative) emotional expression on the N170 have been reported in 3- to 4-year-olds (Dawson et al., 2004) and 5-year-olds (de Haan et al., 1998). However, a recent study by Batty and Taylor (2006) investigating facial expression processing from early childhood to adolescence indicated that early effects of negative emotion do not occur at the face-specific N170 until the age of 14–15. The latencies of these early effects at both P1 and N170 are usually somewhat delayed in infants and children compared to adults. Although the P1 and N170 results are not entirely consistent across developmental studies, the above-mentioned ERP studies underline the rapid (< 200 ms) processing of emotional expressions in visual areas in both adults and children.

This study investigated effects of SF manipulations on the early processing of fearful facial expressions in the visual cortex in groups of 3- to 4-year-old, 5- to 6-year-old, and 7- to 8-year-old children using the event-related potential technique. During a passive viewing task, we examined whether the effects of emotion expression at early visual information processing stages (P1 and N170) are primarily mediated by global LSF cues, as in adults, or by detailed HSF information. Through administration of an additional active behavioral task in which participants were required to categorize rapidly negative (fearful) or neutral face expressions, we aimed to explore the development of the role of spatial frequency on emotion recognition at the behavioral level. That is, we tested whether a LSF or HSF advantage for the processing of emotion would be reflected in reaction times. This behavioral task was only administered to the 5- to 6-year-old and 7- to 8-year-old children.

Method

Participants

This study included 20 children (11 female, 9 male) between 3 and 4 years (mean age = 3.10 years), 25 children (12 female, 13 male) between 5 and 6 years (mean age = 6.1 years), and 25 children (12 female, 13 male) between 7 and 8 years (mean age = 7.8 years) old. The children were recruited at an elementary school in Kerkrade (Netherlands). The 3- to 4-year-old group originally consisted of 27 participants, but 7 children dropped out due to ocular or muscular artefacts or an insufficient number of trials in which they looked at the screen.

To ensure that all children performed in the normal cognitive range (IQ > 90) for their age, children completed an IQ test. All 3- to 4-year-old children successfully completed the SON–R 2½–7 (Tellegen, Winkel, Wijnberg-Williams, & Laros, 1998), and the 5- to 6-year-old and 7- to 8-year-old children performed two subtests of the WISC–III (Wechsler, 1991): the block design and vocabulary tests. The estimated total IQ score derived from these subtests has a mean reliability of .94 and a mean validity of .91 compared to the complete WISC–III (Spreen & Strauss, 1998). (See Table 1 for mean total IQ scores for each age group.) No children were excluded based on IQ. Additionally, to check for behavioral problems, parents completed the Child Behavior Checklist (CBCL; Achenbach, 1991). The CBCL is an instrument used for the detection of behavioral problems in children. In the 7- to 8-year-olds, 3 children (of 28) were excluded before experimental testing took place because they scored in the clinical range (> 63) on the Internalizing (I), Externalizing (E), and Total Problem subscales of the CBCL (Achenbach, 1991). Participants had no neurological history and had normal or corrected to normal vision as verified by their parents. In the Netherlands, all children get a standard visual checkup at the age of 3 or 4 years. All parents gave written informed consent for their child's participation in the study. A local ethical committee of the Faculty of Psychology at Maastricht University, Netherlands, approved the experimental procedure.

Table 1
Mean Full-Scale IQ Scores (SD in Parentheses) for the Three Age Groups

	Full scale IQ	Range
3–4 years	123.0 (9.3)	105–144
5–6 years	114.6 (10.2)	90–131
7–8 years	108.9 (9.9)	90–135

Note. Standard deviations are given in parentheses.

Stimuli and Task Procedure

Face stimuli consisted of 16 grayscale images (8 males, 8 females), half of which depicted a neutral expression, while the other half depicted a fearful expression. Fearful and neutral expressions were from different individuals. The photographs were taken from the NimStim Face Set (http://www.macbrain.org/resources.htm; Tottenham, Borscheid, Ellertsen, Marcus, & Nelson, 2002) and have been shown to evoke emotional effects at the level of the N170 in adults (Blau et al., 2007). Face images included European American and African American models. Fearful and neutral faces were equally balanced across race. Face pictures were trimmed to remove external features (neck and hairline). All pictures were fitted in a gray frame of 500 × 700 pixels. Each face subtended 6.3° of visual angle at a distance of 113 cm. The HSF images were created by filtering the original photographs using a high-pass cutoff of ≥ 6 cpd of visual angle (see Figure 1). The LSF images were created using a low-pass filter of ≤ 2 cpd of visual angle. Filtering was performed in Matlab (The Mathworks, Natick, MA) using a set of Gaussian filters.

The task consisted of four blocks, each containing 73 trials. Within each block, 64 faces and nine animation figures were presented on a gray background in randomized order. All faces were presented for 500 ms with an interstimulus interval of 1600–1800 ms. Participants were instructed to maintain fixation and to attend to all pictures. They had to press a response button as soon as they saw an animation figure on the screen and refrain from responding to all other images. This task was used to maintain the participant's attention during stimulus presentation. Short breaks were given between blocks. A video camera situated next to the screen recorded the child's gaze behavior. For 3- to 4-year-olds, looking behavior was coded offline, whereas it was monitored online for the 5- to 6-year-olds and 7- to 8-year-olds.

After the electroencephalogram (EEG) measurement, 5- to 6-year-old and 7- to 8-year-old children performed an additional reaction time task in which they had to decide as quickly and accurately as possible whether faces looked fearful or "usual" (neutral). Presentation time and interstimulus intervals were kept the same as in the initial ERP task. Participants started with a practice block that contained three phases. In the first phase, participants

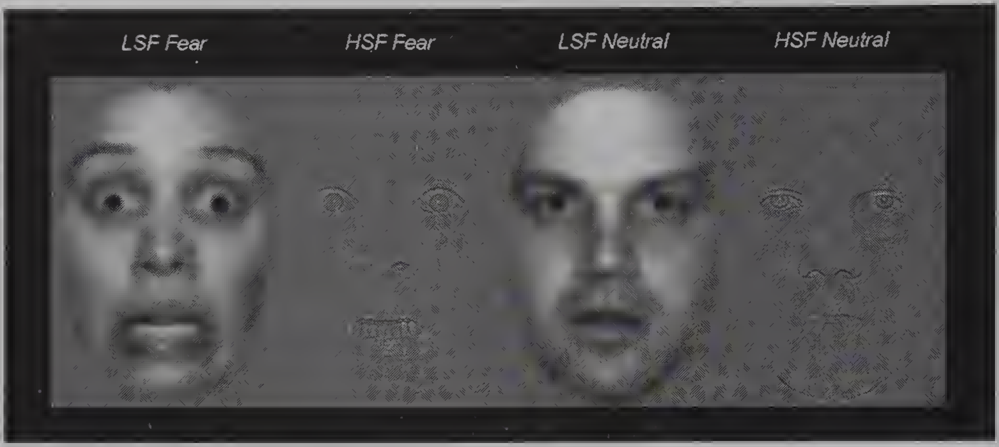

Figure 1. Examples of fearful and neutral low spatial frequency (LSF; < 2 cpd) and high spatial frequency (HSF; > 6 cpd) face stimuli.

were presented with a face of a lion with a fearful expression and were asked: ''How does the lion look?'' Incorrect answers were corrected by the experimenter. Thereafter participants were presented with a face of a lion that looked neutral and were asked: ''How does the lion look?'' Incorrect answers were again corrected by the experimenter. In the second phase, participants were presented with a block of 32 trials in which they had to decide whether the face of the lion looked ''usual'' or ''fearful'' by pressing a left- or right-hand button. The duration of stimulus presentation was locked to the button response. In the third phase, participants had to perform the same task as in Phase 2, but now with experimental task parameters: a fixed stimulus duration of 500 ms with an interstimulus interval of 1600–1900 ms. After the last phase, participants were told that they now had to perform a similar task that contained faces of humans instead of lion faces. Half of the stimuli (neutral) required a left button press whereas the other half (fearful) required a right button press. Left and right button presses were counterbalanced across participants. Right–left assignment was the same in the training and test conditions.

The task contained the same number of stimuli (256) as the initial task ERP but was divided into eight blocks. Furthermore, no animation figures were presented between trials.

ERP Recordings

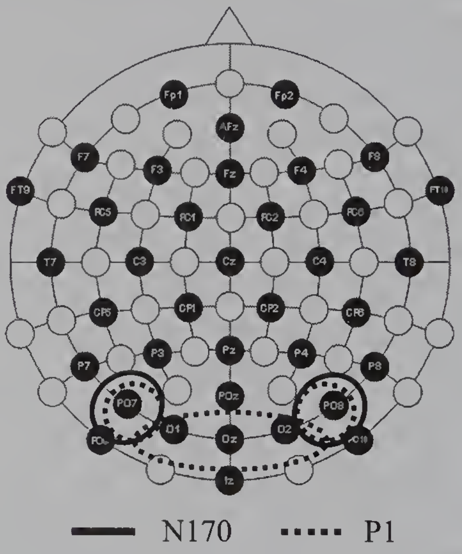

Figure 2. Scalp locations of the 36 electrodes.
Note. Mean amplitude and latency of the P1 were measured at pooled electrode sites: OZ/O1/O2/PO7/PO8. Mean amplitude and latency of the N170 were measured at occipito-temporal electrodes PO7/PO8.

Event-related brain potentials were recorded via a QuickCap (Compumedics, Victoria, Australia) containing 60 electrodes, of which 37 electrodes were used. The electrodes were placed according to the 10–20 system with intermediate positions (see Figure 2) and comprised Fp1/2, Fz, F3/4, F7/8, FC1/2, FC5/6, FT9/10, Cz, C3/4, T7/8, CP1/2, CP5/6, Pz, P3/4, P7/8, POz, PO7/8, Oz, O1/2, Iz, and PO9/10 plus a ground electrode at AFz.

Four additional electrodes placed above and below the left orbit and on the outer canthus of each eye were used to monitor vertical and horizontal eye movements. All electrodes were referenced to the left mastoid online and A2 was measured as an active electrode. Impedances were kept below 20 kΩ. A continuous EEG was recorded with a 500 Hz sampling rate and a band-pass filter of 0.01–200 Hz. The EEG data were analyzed offline using ''Vision Analyser'' software (Brain Products, Munich, Germany). The EEG data were epoched offline into 1500-ms periods, starting 200 ms prior to and ending 1300 ms after stimulus onset. Thereafter, the epochs were filtered (0.1–30 Hz), and artefacts from horizontal eye movements and blinks were reduced with the algorithm of Gratton, Coles,

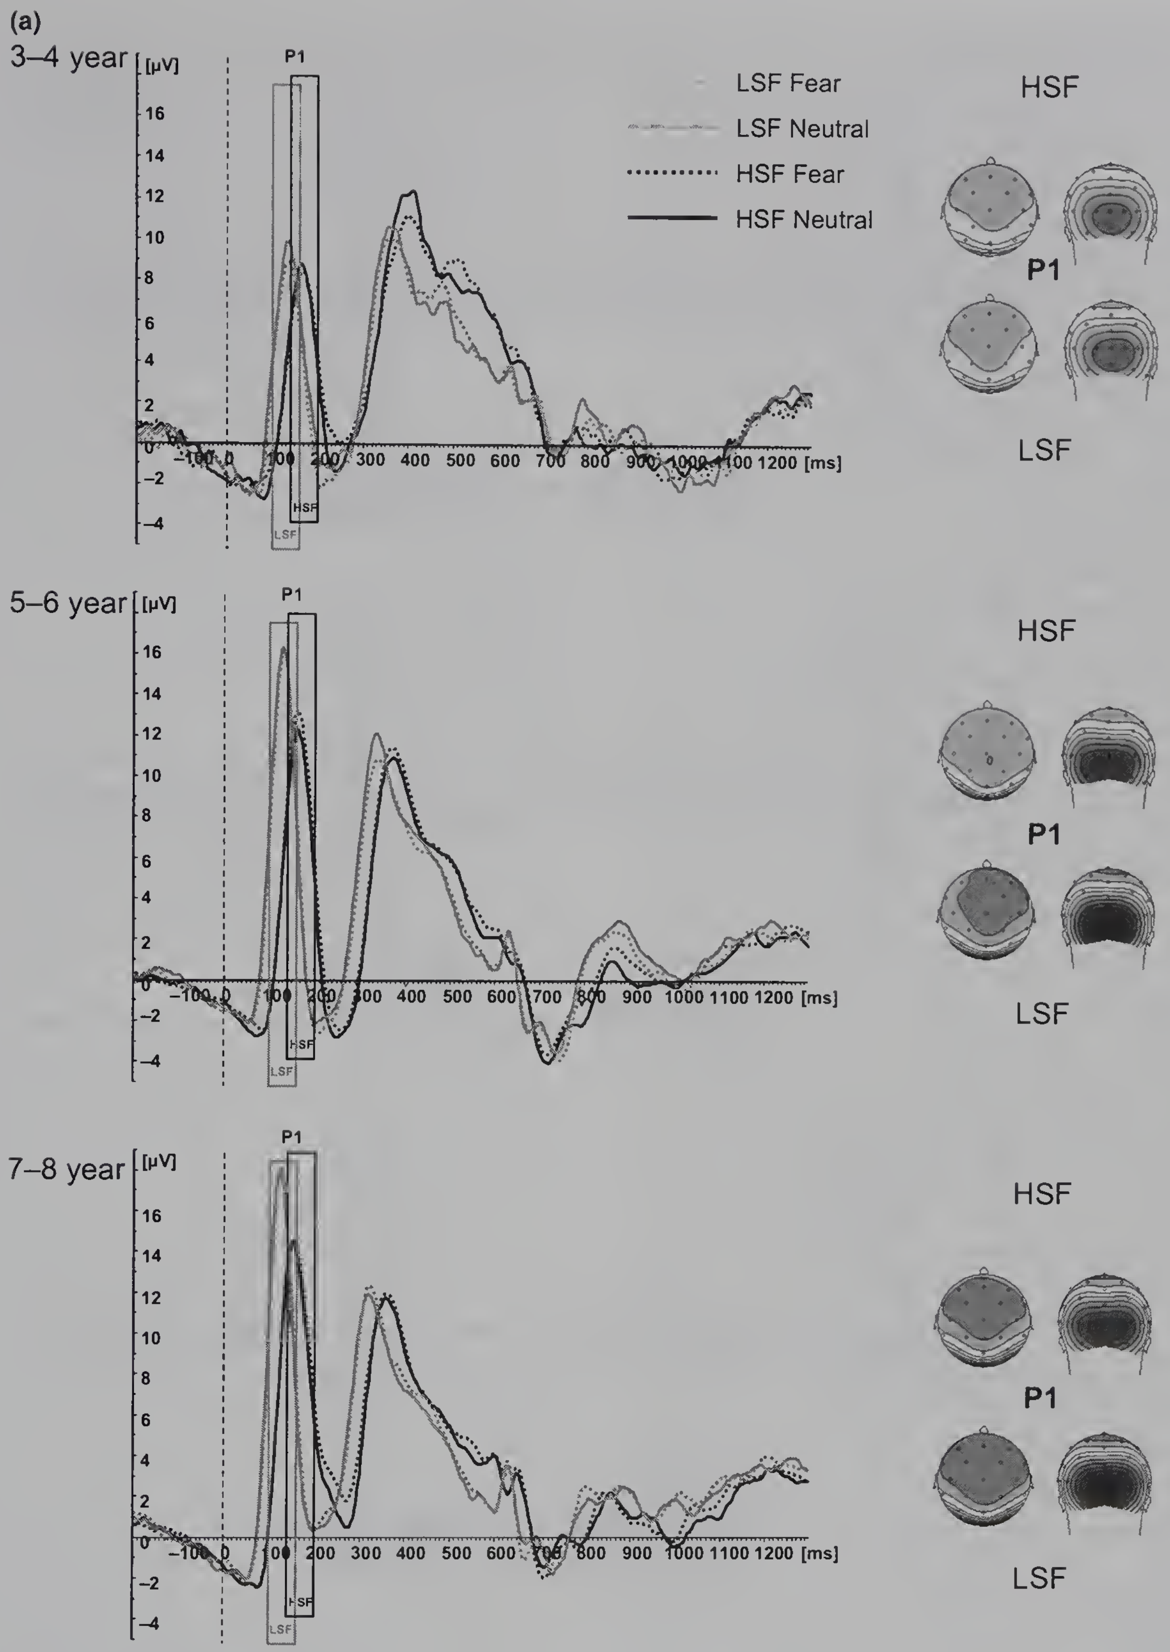

Figure 3. (a) Grand-average waveforms for 3- to 4-year-old, 5- to 6-year-old, and 7- to 8-year-old children at pooled electrodes (Oz/O1/O2/PO7/PO8), from which the P1 was extracted. In addition, the topographical distribution of the P1 is shown.

Note. The gray (low spatial frequency [LSF]) and black (high spatial frequency [HSF]) windows indicate the time windows over which P1 amplitude averages were calculated and P1 peak latency was extracted for statistical analysis. Note that because there is a difference between the way in which the grand-average waveforms (displayed in a and b) and the data used for statistical analysis are calculated (mean amplitudes across a predefined window; see Figure 4), the values in the current graphs may differ from the values used for statistical analysis (displayed in Figure 4).

(b) Grand-average waveforms for 3- to 4-year-old, 5- to 6-year-old, and 7- to 8-year-old children at electrodes PO7 and PO8, from which the N170 was extracted. In addition, topographical distributions of the N170 for HSF and LSF stimuli are shown.

Note. The gray (LSF) and black (HSF) windows indicate the time windows over which N170 amplitude averages were calculated and N170 peak latency was extracted for statistical analysis.

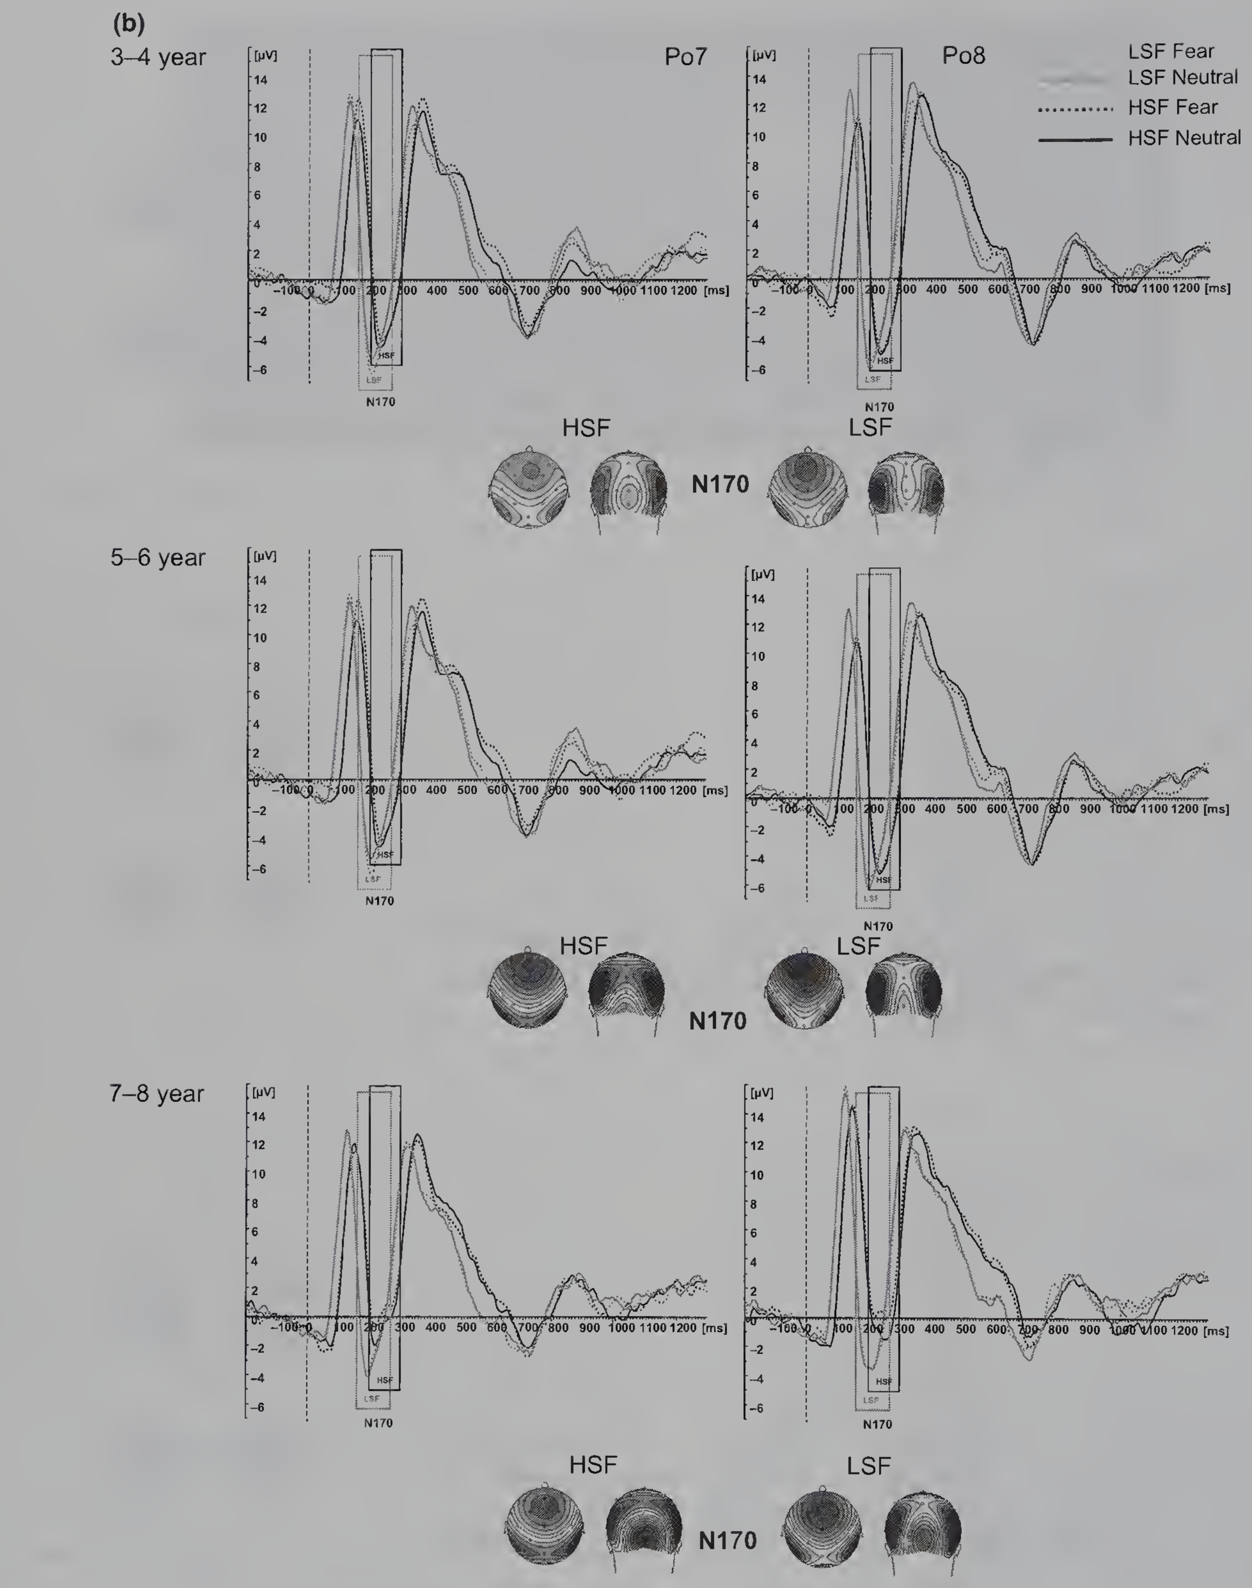

Figure 3. (Continued).

and Donchin (1983). After baseline correction (–200 to 0), trials that contained EEG artefacts (± 75 μV) were rejected from the data set. Furthermore, trials during which the child was not looking at the screen were discarded. Separate ERP averages were computed for all participants for the four stimulus conditions (SF: HSF, LSF) × (emotion: fear, neutral). Finally, the data were rereferenced to an average reference.

According to Cacioppo, Tassinary, and Berntson (2000), a minimum of 20 electrodes are sufficient for average references calculation.

Data Analysis

Based on topographies (spherical spline calculation) and peak maxima (see Figures 3a and 3b), regions or electrodes of interest were defined for

Table 2
Time Windows and Electrodes for Mean Amplitude and Latency Extraction for P1 and N170

ERP peak	LSF	HSF	Electrodes
P1	100–160	140–200	PO7, PO8, Oz, O1, O2
N170	170–270	200–300	PO7, PO8

Note. ERP = event-related brain potential; LSF = low spatial frequency; HSF = high spatial frequency.

both the P1 and N170 components (see Figure 2). Time windows for the components of interest (see Table 2) were chosen through visual inspection of the grand-average waveforms in all groups (see Figures 3a and 3b), which show a clear latency shift between LSF and HSF ERPs and show emotion effects (amplitude difference between fear and neutral) at the chosen time points. To measure P1 and N170 amplitudes, mean area amplitudes across a predefined time window (see Table 2) were used instead of peak amplitudes for two reasons. First, emotional effects were present across a broader time window and did not occur only at the peak (see Figures 3a and 3b). Second, mean areas are less sensitive to high-frequency noise then peak amplitudes (Luck, 2005).

The three groups differed in mean number of total trials included in the analyses, $F(2, 67) = 57.26$, $p < .001$, with fewer trials for the 3- to 4-year-olds (high neutral [HN] = 41, *SD* = 11, range = 25–64; high fear [HF] = 42, *SD* = 10, range = 27–62; low neutral [LN] = 43, *SD* = 9, range = 28–63; low fear [LF]: 43, *SD* = 10, range = 27–64) compared to the 5- to 6-year-olds (HN = 59, *SD* = 8, range = 34–64; HF = 59, *SD* = 7, range = 38–64; LN = 59, *SD* = 8, range = 33–64; LF = 59, *SD* = 8, range = 33–64) and 7- to 8-year-olds (HN = 61, *SD* = 5, range = 40–64; HF = 60, *SD* = 5, range = 43–64; LN = 60, *SD* = 5, range = 41–64; LF = 61, *SD* = 5, range = 48–64). Mean areas do not become biased when the noise level increases due to different trial numbers. Consequently, it is legitimate to compare mean amplitude measurements from waveforms based on different numbers of trials, whereas this is not legitimate for peak amplitude measurements (Luck, 2005). However, note that the lowest number of total trials included in the analysis ($n = 25$) can still be considered high. The mean amplitude of the P1 was extracted from a pooled set of occipito-temporal electrodes: PO7/PO8/Oz/O1/O2 (see Figure 2). The amplitude data were subjected to a 2 (SF: HSF, LSF) × 2 (emotion: fear, neutral) × 3 (group: 3- to 4-year-olds, 5- to 6-year-olds, 7- to 8-year-olds) analysis of variance (ANOVA). The mean amplitude of the N170 was extracted from electrodes PO7 and PO8 (see Figure 2). N170 data were subjected to a 2 (SF: HSF, LSF) × 2 (emotion: fear, neutral) × 2 (hemisphere: PO7, PO8) × 3 (group: 3- to 4-year-olds, 5- to 6-year-olds, 7- to 8-year-olds) ANOVA. Because the topographical distribution of the P1 did not show any laterality effects, we did not include this factor in the analysis. The location from which the different components were extracted is consistent with several ERP studies in children (see, e.g., Batty & Taylor, 2006; Dawson et al., 2004).

Because the grand averages (see Figures 3a and 3b) showed clear effects of SF on peak latency at the P1 and N170, we also analyzed peak latency for HSF and LSF. Although peak latencies, like peak amplitudes, are prone to high-frequency noise and have other shortcomings, there are not many good alternatives and so they are often the best measure (Luck, 2005). Based on the suggestions of Luck (2005), we took the following precautions: (a) We filtered out the high-frequency noise in the waveforms by filtering the preprocessed data with an additional 10-Hz low-pass filter (note, however, that using a 30-Hz low-pass filter, the latency results were replicated). (b) We used a peak detection algorithm that looked for local peak maxima rather than an absolute peak measure. When searching for local maxima, the automatic peak detection algorithm looks for extreme values within a given interval and considers the edge values only if this search fails. The difference between a local and an absolute maximum is that, in searching for an absolute maximum, the edge points of the intervals are found as peaks if the value there is greater (or less) than all values within the interval. (c) We only analyzed the effect of SF (which was clearly present in the data; see Figures 3a and 3b) in the different age groups, which resulted in a relatively high number of trials *per condition* (maximum = 128). Previous studies in adults have indicated that interactions between SF and emotion affect P1 and N170 amplitude only (Pourtois et al., 2005; Vlamings et al., 2009). P1 latency was extracted from a pooled set of occipito-temporal electrodes: PO7/PO8/Oz/O1/O2 (see Figure 2). P1 latency was subjected to a 2 (SF: HSF, LSF) × 3 (group: 3- to 4-year-olds, 5- to 6-year-olds, 7- to 8-year-olds) ANOVA. N170 latency was derived from electrodes PO7 and PO8 (see Figure 2) and these data were subjected to a 2 (SF: HSF, LSF) × 2 (hemisphere: PO7, PO8) × 3 (group: 3- to 4-year-olds, 5- to 6-year-olds, 7- to 8-year-olds) ANOVA.

Reaction times (only reaction times between 150 and 2100 ms after stimulus onset were included in the analysis) and percentage hits from the separate categorization task were subjected to a 2 (SF: HSF, LSF) × 2 (emotion: fear, neutral) × 2 (group: 5- to 6-year-olds, 7- to 8-year-olds) ANOVA. Four participants (three 5- to 6-year-olds and one 7- to 8-year-old) were excluded (significant outliers) from the analysis because they had too many misses.

When statistically significant first-, second-, or third-order interactions were found, these were further tested by looking at partial interactions in a fixed order (SF, emotion, hemisphere, and group). The higher order interactions had to be significant before lower order interactions were considered. When testing of significant interactions did not lead to significant results, these are not mentioned in the study.

Finally, for the 5- to 6-year-olds and 7- to 8-year-olds, correlation analyses were performed between behavioral measures (reaction times and percentage correct) and P1 and N170 amplitude and latency data in the different conditions.

Results

Grand averages and topographical distributions of the P1 and N170 are depicted in Figures 3a and 3b. The mean values and standard errors of mean amplitude and latency measures of the P1 and N170 used for statistical analysis are depicted in Figures 4 and 5.

P1 Amplitude

The overall four-way ANOVA revealed an interaction between SF and emotion, $F(1, 67) = 5.42$, $p < .05$, $\eta^2_p = .08$. Pairwise comparisons indicated significantly higher P1 amplitudes for fearful compared to neutral faces presented at HSF, $t(69) = 2.61$, $p < .05$, $\eta^2_p = .09$ (see Figures 3a and 4), whereas the difference between neutral and fearful faces was not significant for LSF faces. Furthermore a main effect of group was found irrespective of SF, $F(2, 67) = 10.22$, $p < .001$, $\eta^2_p = .23$, showing that P1 amplitudes of 3- to 4-year-old children were larger than those in 5- to 6-year-old children, $t(43) = -3.65$, $p < .01$, Cohen's $d = -1.39$, and 7- to 8-year-old, $t(43) = -4.73$, $p < .001$, Cohen's $d = -1.14$ (see Figures 3a and 5). Other main effects were not found.

P1 Latency

The analysis of peak latency of P1 only revealed a significant main effect of SF, $F(1, 67) = 549.59$, $p < .001$, $\eta^2_p = .89$, with HSF faces showing longer P1 latencies than LSF faces (see Figures 3a and 5).

N170 Amplitude

The overall four-way ANOVA revealed a significant interaction between SF and emotion, $F(1, 67) = 9.20$, $p < .01$, $\eta^2_p = .10$. There were no main effects. As for P1, pairwise comparisons indicated a significant effect of emotion for HSF faces only. For the N170, however, neutral HSF faces elicited significantly higher amplitudes than HSF fearful faces, $t(69) = -3.67$, $p < .001$, $\eta^2_p = .11$, whereas there was no effect of emotion for LSF faces (see Figures 3b and 4).

N170 Latency

For N170 peak latency, we only found a significant SF × Group interaction, $F(2, 67) = 4.42$, $p < .05$, $\eta^2_p = .12$ and no main effects. The SF effect was significant in each of the age groups, with LSF faces showing shorter peak latencies than HSF faces: 3- to 4-year-olds, $t(19) = -5.04$, $p < .001$, $\eta^2_p = .57$; 5- to 6-year-olds, $t(24) = -13.09$, $p < .001$, $\eta^2_p = .88$; 7- to 8-year-olds, $t(24) = -18.34$, $p < .001$, $\eta^2_p = .93$ (see Figures 3b and 5). Further analysis revealed a significant effect of group for LSF faces only, $F(2, 67) = 3.68$, $p < .05$. Three- and 4-year-old children had longer N170 latencies than 7- to 8-year-old children, $t(43) = 2.54$, $p < .05$, $\eta^2_p = .10$ (see Figures 3b and 5), when presented with an LSF face, whereas there was no difference between the 3- to 4-year-olds and 5- to 6-year-olds. Post hoc correlation analyses indicated a significant negative correlation between age in months (including all age groups) and latency for LSF faces $r = -.27$, $p < .05$. This effect was absent for HSF faces.

Percentage Hits—Categorization Task

Analysis of the percentage hits recorded in the categorization task in the 5- to 6-year-olds and 7- to 8-year-olds indicated a marginally significant Group × Emotion interaction, $F(1, 44) = 3.99$, $p = .052$, $\eta^2_p = .08$; 7- to 8-year-olds performed slightly better on neutral compared to fearful faces, $t(23) = -3.02$, $p < .01$, $\eta^2_p = .28$, but there was no stimulus difference for 5- to 6-year-olds. When testing group differences for neutral and fearful stimuli, 5- to 6-year-olds had fewer hits in the neutral condition compared to 7- to 8-year-olds, $t(44) = -2.58$, $p < .05$, $\eta^2_p = .13$. There was a significant positive correlation between age in months and percentage

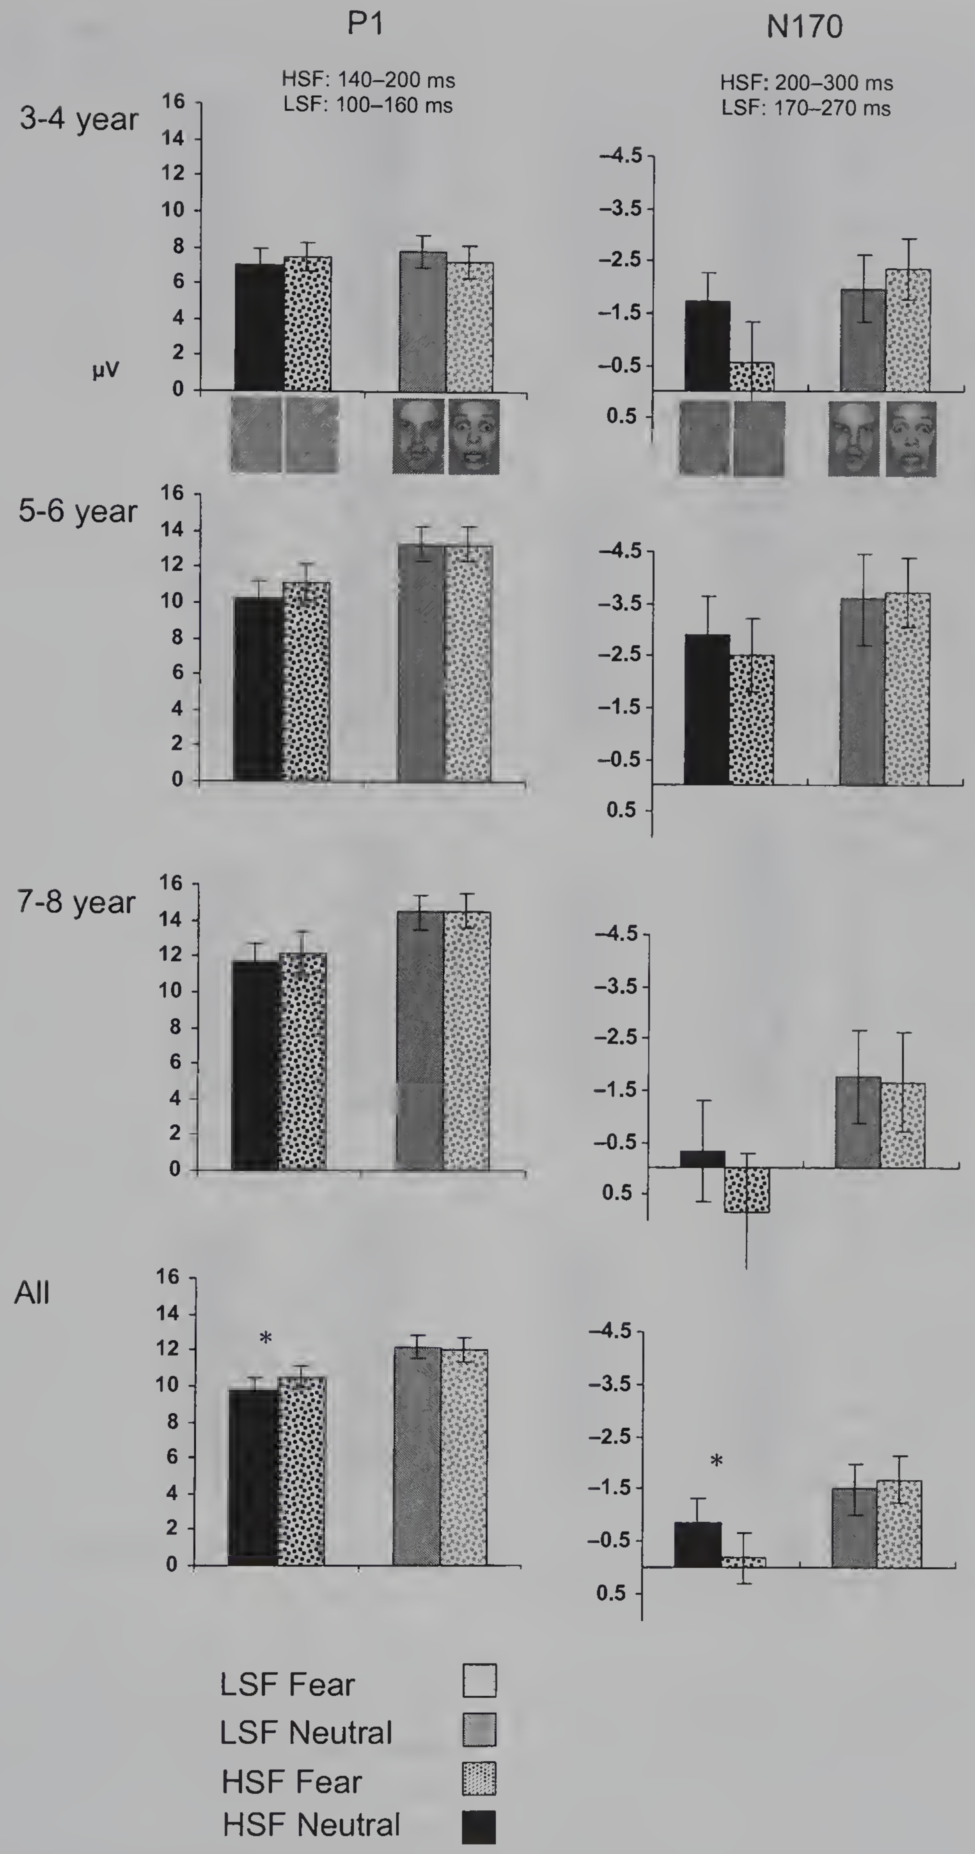

Figure 4. Bar graphs of the mean amplitudes (+*SE*) of the P1 and N170 in all stimulus conditions (high spatial frequency [HSF] fear, HSF neutral, low spatial frequency [LSF] fear, LSF neutral) are shown separately for each age group.

Note. Note that because there is a difference in the way in which the grand averages (displayed in Figures 3a and 3b) and the data used for statistical analysis, shown in the bar graphs in this figure, are calculated, the values in the current graphs may differ from the values displayed in Figures 3a and 3b. In the top row, the windows over which the amplitude averages were calculated are reported for P1 and N170.

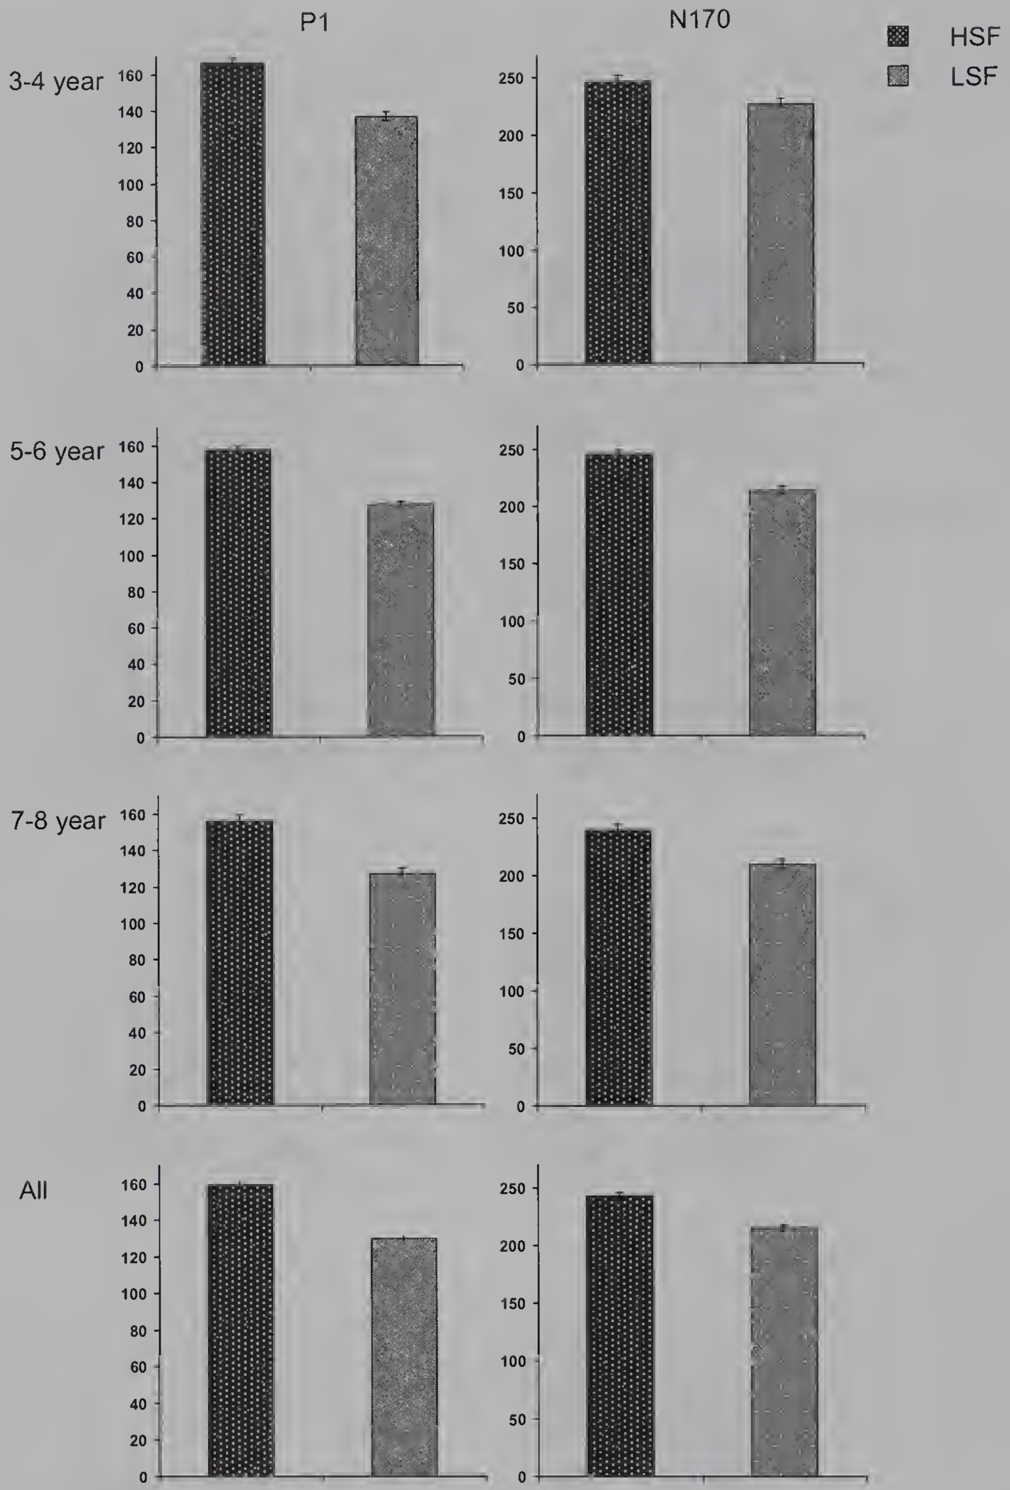

Figure 5. Bar graphs of the mean latencies (+*SE*) of the P1 and N170 in all stimulus conditions (high spatial frequency [HSF] and low spatial frequency [LSF]) are shown separately for each age group.

of correct trials in the neutral condition, $r = .35$, $p < .05$, but not in the fearful condition.

Reaction Times—Categorization Task

Analysis of the reaction times revealed a marginally significant effect of emotion, $F(1, 44) = 3.96$, $p = .053$, $\eta^2_p = .08$, indicating faster reaction times to recognize fearful than neutral faces (see Table 3). In addition, we found a main effect of SF, $F(1, 44) = 39.69$, $p < .001$, $\eta^2_p = .74$. Participants were faster, overall, in categorizing LSF faces than HSF faces (see Table 3).

Correlation Between Behavioral Performance and ERP Measures

In none of the conditions were significant correlations between reaction times or percentage hits and P1/N170 latency or amplitude found.

Table 3
Mean Reaction Times (RT) and Percentage Hits for All Stimulus Conditions Averaged Across 5- to 6-Year-Old and 7- to 8-Year-Old Children

	LSF		HSF	
	Neutral	Fear	Neutral	Fear
Hit RT (years)				
5–6	1001 (45)	988 (44)	1030 (43)	1019 (44)
7–8	986 (29)	961 (33)	1026 (31)	1002 (31)
Hit percentage (years)				
5–6	70 (5)	75 (3)	69 (4)	72 (4)
7–8	83 (3)	81 (3)	81 (3)	75 (3)

Note. Standard errors are given in parentheses. LSF = low spatial frequency; HSF = high spatial frequency.

Discussion

The aim of this study was to investigate the effect of manipulation of the spatial frequency content (LSF and HSF) of face stimuli on the rapid processing of negative (fearful) and neutral facial expressions in the visual cortex of 3- to 8-year-old children. Recent studies have revealed that, in adults, early effects of facial emotion content (< 200 ms) on ERP components above the visual cortex (P1 and N170), are primarily mediated by LSF information (Pourtois et al., 2005; Vlamings et al., 2009).

In contrast, in this study we found that the early effects of emotion expression detection at the P1 were driven primarily by more detailed HSF information in all children (such as contours of the eyes, eyebrows, mouth, and so on). This was shown by higher P1 amplitudes for fearful compared to neutral faces for HSF images only. Similar enhanced P1 amplitudes in response to broadband fearful face stimuli (containing all frequencies) are typically interpreted as reflecting involuntary capture of attention by fear (e.g., Pourtois et al., 2004, 2005). Whereas this Emotion × SF interaction effect was found for all children, a group main effect indicated that P1 amplitude decreased with age, consistent with Batty and Taylor (2003, 2006). These authors suggested that this developmental effect reflects automatization of visual processing in general. However, main effects of group on ERP amplitude are difficult to interpret and might also reflect structural brain changes. To exclude the possibility that the P1 findings were influenced by unintended differences in low-level visual characteristics between neutral and fearful faces resulting from filtering, additional analyses were performed. These analyses indicated that the spatial frequency content of the two expression types did not differ substantially, making it highly unlikely that such differences influenced the present results. Furthermore, the present results show that besides for P1, also for the face-specific N170, effects of emotional expression are driven by a different type of SF information compared to adults (Vlamings et al., 2009).

A possible explanation for this developmental effect must take into account findings that consistently show that infants just a few months old already have a "preference" for fearful faces, as shown by longer looking times (Kotsoni, de Haan, & Johnson, 2001; Nelson & Dolgin, 1985; Peltola, Leppänen, Mäki, & Hietanen, 2009) and larger ERP responses to fearful than other faces (de Haan, Belsky, Reid, Volein, & Johnson, 2004; Leppänen, Moulson, Vogel-Farley, & Nelson, 2007; Nelson & de Haan, 1996). This early preference for fear is most probably mediated by LSF cues since, due to immaturity of the visual system, 6- to 12-month-old infants have very little sensitivity to HSF (de Heering et al., 2008; Slater & Sykes, 1977). Integrating this literature with the present data yields the following developmental pattern: During infancy, the early visual processing of fearful expressions is (most strongly) mediated by LSF cues, followed by a shift to HSF cues in childhood as is shown by the present ERP data, then returning to the use of LSF cues in adulthood (Pourtois et al., 2005; Vlamings et al., 2009).

The enhanced use of HSF cues for early visual processing of fear during childhood, as opposed to LSF cues in adults, might be linked to immaturity of the subcortical face-processing route (see the Introduction). This route makes use of LSF and is suggested to boost P1 amplitudes to fearful LSF faces through direct modulating feedback signals coming from the amygdala (Pourtois et al., 2005). In support of this hypothesis, Cunningham, Bhattacharyya, and Benes (2002) found that amygdala–cortical connectivity continues to mature into adolescence, at least in the prefrontal areas. However, such an explanation would be difficult to reconcile with findings suggesting that the subcortical face-processing route is already functional in newborns and probably plays a crucial role in the bias for fearful expressions that is already present at this age (see for review Johnson, 2005; Morton & Johnson, 1991). Finally, the conclusion that early LSF-based processing of fearful expressions in adults is mediated by a rapid subcortical processing route is, as yet, only derived from indirect evidence (see Pourtois et al., 2005; Vuilleumier et al., 2003). It is possible that this early, LSF-based, facial emotion processing in the visual cortex results from a rapid feedforward cortical projection within the visual system itself. Future studies, possibly using fMRI (or a combination of fMRI and EEG), should be aimed at further disentangling these possibilities.

An alternative explanation that takes into account both the maturation of the visual system and the influence of developmental differences in expertise with face processing might better fit the data. As the ability to resolve HSF only reaches maturity at 3–4 years (e.g., Adams & Courage, 2002), children presumably might not be able to process relevant HSF emotional cues before that age. This is supported by findings showing that infants use mainly LSF cues for face processing (de Heering et al., 2008). At the age of 3–4 years, however, the ability to resolve HSF information reaches maturity, and HSF information might become most efficient for the rapid extraction of emotion, as found in this study at least up to 8 years. The developmental shift to the use of LSF cues again in adulthood, as seen in both P1 and N170, might in turn be related to increased expertise with facial expressions and faces in general.

Some evidence for such an expertise account comes from a study by Schyns and Oliva (1999), showing that adults more frequently used LSF information for face identification when they were familiarized with faces by training. A similar effect was found for object identification by Viggiano, Righi, and Galli (2006). In addition, several studies show stronger configural processing (i.e., a larger inversion effect) for face stimuli for which participants have expertise (see for review McCleery et al., 2008; Parr & Heintz, 2008), and LSFs are known to play an important role in such configural face processing (Flevaris, Robertson, & Bentin, 2008; Goffaux, Gauthier, & Rossion, 2003; Goffaux, Hault, Michel, Vuong, & Rossion, 2005).

Surprisingly, the HSF emotion effect in the 3–8-year-old children at the N170 was opposite to that of the P1. The P1 data suggest increased processing of fearful HSF stimuli, while, at the N170, amplitudes were larger in response to neutral than fearful HSF stimuli. This might be due to ambiguity of neutral faces for young children. A recent study showed that before the age of 9 years, children often rate neutral faces as happy or sad (Durand, Gallay, Seigneuric, Robichon, & Baudouin, 2007; see also Carlson, Felleman, & Masters, 1983; Felleman, Barden, Carlson, Rosenberg, & Masters, 1983; Reichenbach & Masters, 1983). In this study, the oldest (7–8 years old) children also correctly categorized a higher percentage of neutral faces than 5- to 6-year-olds. Additionally, Thomas et al. (2001) demonstrated greater amygdala activity in response to neutral faces than fearful faces in children than adults (see also Tottenham, Hare, & Casey, 2009). It was argued that this enhanced activity might signal increased effort invested in the decoding of the neutral face expression that is perceived as ambiguous by children. Such an explanation would be congruent with the fact that amplitudes to neutral faces were only enhanced for the N170 and not the P1 in this study. As opposed to the P1, which is assumed to be primarily sensitive to low-level visual processing or attentional manipulations, the N170 is thought to be especially involved in structural encoding of faces (Jacques & Rossion, 2006; Nobre, Rao, & Chelazzi, 2006; Taylor, 2002; Valdes-Sosa, Bobes, Rodriguez, & Pinilla, 1998).

With respect to the latencies of the P1 and N170, we found faster latencies for processing of LSF compared to HSF stimuli, irrespective of facial expression, which is consistent with findings in adults for facial (Halit, de Haan, Schyns, & Johnson, 2006; Hsiao, Hsieh, Lin, & Chang, 2005; McCarthy, Puce, Belger, & Allison, 1999) and nonfacial (Mihaylova, Stomonyakov, & Vassilev, 1999; Musselwhite & Jeffreys, 1985) stimuli. Similar effects were found with respect to reaction times in the current behavioral categorization task. The temporal precedence of LSF is consistent with findings that the neuronal pathways sensitive to LSF and HSF have dissociable time scales, with faster cortical arrival of information that is processed in the LSF-sensitive magnocellular pathway (see for review Laycock, Crewther, & Crewther, 2007).

Importantly, the latency of the N170 decreased in the LSF condition with increasing age, whereas there were no significant age effects for processing of HSF faces. Faster N170 latencies with increasing age have previously been reported for face stimuli containing all SF frequencies (see for review Taylor, Batty, & Itier, 2004). This study thus suggests that this decrease in N170 latency to unfiltered faces might be caused specifically by faster extraction of LSF information. In contrast to these developmental effects on N170 latency for LSF, no age effects were found with respect to P1 and N170 amplitude. That is, early effects of emotion at P1 and N170 amplitude were primarily driven by HSF, and this did not change with age. Integration of the latency and amplitude results suggests that although children seem to more rapidly extract LSF information for face processing with age, this information does not yet drive emotional processing during early face-processing stages.

Finally, in a behavioral task, we investigated whether an LSF or HSF advantage for the processing of facial expressions would be reflected in reaction times to an active categorization task. Like adults (Vlamings et al., 2009), children decided more quickly that a face was fearful than that it was neutral, which is consistent with the finding that stimuli that signal threat receive preferential attention over neutral stimuli (see for review Holmes, Green, et al., 2005). The lack of an interaction between emotion and SF suggests that emotional expressions are recognized based on LSF as well as HSF information at later information processing stages (at response level). This is supported by data from another recent behavioral study that indicated that both HSF and LSF cues are used for emotion identification in typically developing children (one age group: 6–16 years; Deruelle, Rondan, Salle-Collemiche, Bastard-Rosset, & Da Fonséca, 2007). We did not find evidence for an association between behavioral performance and ERP measures suggesting that in this study early and late stages of processing might not be directly linked.

In conclusion, the present data show that just as in adults, 3- to 8-year-old children show enhanced early visual brain responses (P1) to fearful compared to neutral faces. However, whereas prior work showed that this effect was mediated by LSF cues in adults and infants, present data showed that in children more detailed (HSF) face cues were used (such as eyes, mouth, and so on). The absence of an LSF bias for the processing of fear in 3- to 8-year-olds might be explained by a combination of immaturity of the visual system to process HSF information and a lack of expertise with face processing that enables adults to rely on LSF information. Future studies with older age groups should establish when the processing of fear starts to be driven primarily by LSF information. Finally, our data suggest that a developmental latency decrease of the N170 could be linked to faster extraction of LSF cues with age. The present data might be important for research in neurodevelopmental disorders such as autism, for which specific deficits in the processing of LSF have been suggested (see for review Johnson, 2005; Laycock et al., 2007) and might lead to an investigation of how this LSF bias in autism is linked to the development of gaze behavior and face expertise. Finally, it should be noted that due to practical considerations, the present study only included one emotional expression (fear) and that the present effects thus cannot be generalized to general (negative) emotion processing, which should be the subject of a future study.

Typologies of Family Functioning and Children's Adjustment During the Early School Years

Melissa L. Sturge-Apple
and Patrick T. Davies
University of Rochester

E. Mark Cummings
University of Notre Dame

Guided by family systems theory, the present study sought to identify patterns of family functioning from observational assessments of interparental, parent–child, and triadic contexts. In addition, it charted the implications for patterns of family functioning for children's developmental trajectories of adjustment in the school context across the early school years. Two-hundred thirty-four kindergarten children (129 girls and 105 boys; mean age = 6.0 years, *SD* = 0.50 at Wave 1) and their parents participated in this multimethod, 3-year longitudinal investigation. As expected, latent class analyses extracted 3 primary typologies of functioning including: (a) cohesive, (b) enmeshed, and (c) disengaged families. Furthermore, family patterns were differentially associated with children's maladaptive adjustment trajectories in the school context. The findings highlight the developmental utility of incorporating pattern-based approaches to family functioning.

Homes characterized by high levels of interparental discord evidence greater perturbations in parenting and emotional unavailability (e.g., Sturge-Apple, Davies, & Cummings, 2006), as well as overreactive discipline and difficulties controlling or managing children (Lorber & O'Leary, 2005; Stoneman, Brody, & Burke, 1989). In addition, children in families with high levels of interparental discord and parenting difficulties have greater problems in meeting developmental milestones (e.g., Gonzales, Pitts, Hill, & Roosa, 2000; Sturge-Apple et al., 2006; Webster-Stratton & Hammond, 1999). Much of the work from this field of inquiry has utilized variable-based approaches in delineating associations between interparental and parent–child relationships and children's development. However, the moderate relations between interparental and parent–child functioning highlight that there is not a one-to-one correspondence in difficulties across family subsystems (e.g., Erel & Burman, 1995). Thus, although variable-based models of family functioning have been informative, exclusive reliance on linear continua to characterize functioning across family subsystems does not fully capture qualitatively different profiles of communication patterns across family subsystems (Minuchin, 1985). To overcome these limitations, researchers have increasingly called for the utilization of pattern-based approaches toward also identifying nonlinear configurations of relationship qualities across family subsystems (e.g., Belsky & Fearon, 2004; Johnson, 2003; McHale, Kazali, Rotman, Talbot, Carleton, and Lieberson, 2004; O'Connor, Hetherington, & Reiss, 1998). Pattern-based approaches, such as those used in cluster-analytic and latent class techniques, reveal qualitatively different profiles of study variables that are not anchored on a linear or continuous scale.

Family systems theory challenges researchers to extend beyond understanding child development solely in the context of the parent–child relationship by incorporating collective experiences in the broader family unit in models of family process. However, applying family systems theory to developmental research designs remains a formidable challenge (McHale, Kuersten-Hogan, & Rao, 2004). At a conceptual level, employing the family systems paradigm in understanding children's

developmental difficulties necessitates accounts of child adaptation within a rich, but parsimonious, characterization of the interplay among relationships and individuals in the family context (e.g., Cowan & Cowan, 2002; McHale, Kuersten-Hogan, & Lauretti, 1996). By the same token, the incorporation of methodological and analytic advances in studies examining developmental models of family systems has lagged behind as researchers have tended to utilize variable-based methods rather than pattern-based methods to examine interplay among family subsystems. Accordingly, the aims of the present study are to: (a) utilize a pattern-based approach to identify family typologies across multiple family contexts and (b) examine how family typologies are associated with children's socioemotional adjustment in extrafamilial settings, especially the school context.

A central assumption of family systems theory is that interdependencies among relationships within the family are governed by boundaries or implicit rules for accessing materials, resources, and support within the family. Guided by the concept of boundaries, family systems theorists have consistently identified three qualitatively distinct profiles of family interactions characterized by harmony, disengagement, and enmeshment, respectively (e.g., Minuchin, 1974). Harmonious or cohesive families have well-defined, yet permeable boundaries that permit children access to resources (e.g., support, warmth) without undermining relational autonomy with other family members (Cox & Paley, 1997). Relatively warm, emotionally close and agreeable relationships across multiple family subsystems characterize this family type, with negative affect and difficulties effectively managed to prevent spillover from any single subsystem into other family relationships. In contrast, disengaged families have rigid boundaries, manifested in cold, indifferent, unsupportive, and emotionally withdrawn family relationships. Communication across family subsystems is stymied and difficult and family members function as distinct entities rather than part of a unified whole. Finally, the diffuse, thin boundaries of enmeshed families are reflected in emotionally seamless and entangled relationships. Children may experience some degree of warmth and support in these family relationships, but access to these resources occurs at a cost, including the proliferation of hostility and distress from one family subsystem to another, intrusive relationships, and significant restrictions in personal and psychological autonomy. Although other possible family systems are sometimes described in this literature, our tri-partite classification scheme is consistent with Minuchin's conceptualizations stressing boundary determination and differentiation of separate family subsystems (Minuchin, 1974), supported by both clinical and empirical studies (Davies, Cummings, & Winter, 2004; Kerig, 1995; Kretchmar & Jacobvitz, 2002).

Furthermore, family system theorists stress that family patterns must be contextualized, including consideration of developmental transitions and how these transitions may serve as informative catalysts for examining family functioning and children's development (e.g., Cowan, 1991; Minuchin, 1985). Thus, the present study examined how family functioning across multiple systems was associated with children's adjustment over the early school years. As a significant developmental milestone in the lives of children (Alexander & Entwisle, 1988; Cowan, Cowan, Ablow, Johnson, & Measelle, 2005; Perry & Weinstein, 1998; Vecchiotti, 2003), the early school years provide an informative window for examining how family relationship patterns may affect children's adaptation in extrafamilial contexts (Davies, Winter, & Cicchetti, 2006). For example, in navigating stage-salient tasks inherent in adapting to the school context such as establishing self-confidence, academic competence, peer relationships, and behavioral control in the school setting (e.g., Ladd & Burgess, 2001), children may turn to their family as a source of support and protection. Furthermore, numerous developmental theories suggest that children's internalizations of family experiences are used as blueprints for interpreting and responding to novel challenges outside the family (Cassidy, Kirsch, Scolton, & Parke, 1996; Greenberg, Speltz, & DeKlyen, 1993). Thus, dysfunctional family patterns may undermine children's successful adaptation in the school context across multiple domains of functioning.

Previous empirical work has reported linkages between various patterns of family functioning and children's adjustment. Cohesive families have been associated with lower internalizing and externalizing symptoms (e.g., Johnson, Cowan, & Cowan, 1999; Kerig, 1995; McHale & Rasmussen, 1998; Richmond & Stocker, 2006) and better peer relationships (e.g., McHale, Johnson, & Sinclair, 1999). In contrast, enmeshed family patterns have been related to elevated internalizing symptoms in older children and adolescents (Davies et al., 2004; Jacobvitz, Hazen, Curran, & Hitchens, 2004; Kerig, 1995) while disengaged family patterns have been linked with elevated externalizing problems (e.g., Davies et al., 2004; Kerig, 1995). However, despite the developmental significance of children's successful adaptation to school, scant research has examined relations between patterns in family functioning and longitudinal assessments of children's adjustment trajectories across multiple domains during the early school years. As the lone study to examine typologies of family functioning and children's adjustment during the early school years, Johnson (2003) identified three family typologies at kindergarten—cohesive, separate, and enmeshed family patterns—which in turn differentially predicted children's externalizing behaviors in the school context.

The present study seeks to build on the findings reported by Johnson (2003) in several important ways. First, from a methodological standpoint, Johnson utilized a triadic family interaction task in deriving typologies. While this assessment method provides important information regarding the complexity of mother–father–child interactions at a triadic level, the incorporation of assessments of multiple family contexts allows for a richer characterization of family processes. Accordingly, the present study also utilized assessments of family functioning at dyadic and triadic levels, including the interparental relationship, the parent–child dyadic relationship, and the mother–father–child relationship. The inclusion of distinct assessments of multiple systems allows for a comprehensive examination of patterns of functioning in multiple contexts. Second, from a developmental standpoint, Johnson (2003) restricted assessments of children's adjustment to examining changes in externalizing symptoms as a function of family patterns. Progress in understanding how different family patterns may eventuate in children's adjustment difficulties depends upon expanding beyond the usual focus on global assessments of children's psychological symptoms as outcome measures. To this end, the present study simultaneously examined theoretically defined domains of school adjustment (Ladd, 2003), which advocate for examining children's perceptions and appraisals of the school environment, involvement and conformity to classroom activities, and psychological reactions in the school context (e.g., internalizing and externalizing dimensions). Following previous operationalizations of domains of school adjustment, difficulties in emotional adjustment to school were defined as children's perceptions of loneliness, disengagement, and difficulties with peers in the school context (e.g., Buhs & Ladd, 2001), while difficulties in classroom engagement included children's problems in cooperating and actively participating within the context of classroom activities and rules (e.g., Birch & Ladd, 1997; Buhs & Ladd, 2001). Psychological reactions were assessed using internalizing and externalizing symptomatology.

In accordance with predictions derived from family systems theory, we hypothesized that enmeshed family patterns would be more strongly linked with internalizing symptomatology and difficulties in emotional adjustment to school. According to the theory (e.g., Minuchin, 1985), family enmeshment may engender greater internalizing difficulties in the school context through impinging developmental processes at a social-cognitive level (e.g., developing appraisals of the self, especially self-esteem and self-efficacy in external contexts) and social-emotional level (e.g., impinging on autonomy). Drawing from notions in the clinical literature that postulate that children in disengaged families may have a skewed sense of independence and autonomy, lack feelings of loyalty and belonging, and a diminished capacity for interdependence in social situations (e.g., Minuchin, 1974), we also hypothesized that disengaged family patterns would be most strongly linked to externalizing symptoms and difficulties in classroom engagement.

Method

Participants

The data for this study were drawn from a larger project designed to assess linkages between family relationships and children's coping and adjustment (Davies, Sturge-Apple, Winter, Cummings, & Farrell, 2006). The original pool of participants consisted of 236 mothers, fathers, and children. Families were included in the project if they met the eligibility criteria that the family had a child in kindergarten and had lived together for at least 3 years. The retention rate from across the three measurement occasions was 91%, resulting in a sample of 214 families (114 girls and 100 boys). Minimal differences were found between the sample who participated at all three waves and those participants who experienced attrition at any point in time over the two waves ($n = 22$). Therefore, in order to maximize study power, we elected to retain the full sample for study analyses and utilized full-information likelihood when estimating missing data within model analyses. Full-information maximum likelihood (FIML) is a widely accepted and advantageous technique for the imputation of missing data (see Enders, 2001). Two families were identified as multivariate outliers based upon Mahalanobis distance estimates greater than $p = .001$ *derived* from constructs specified in this study and were therefore excluded from the analyses (Arbuckle, 1997). Thus, the final sample for this study consisted of 234 mothers, fathers, and children (129 girls and 105 boys; mean age = 6.0 years, *SD* = 0.50 at Wave 1).

A primary goal of our recruitment strategies was to obtain a sample of families who, on the whole, exhibited diverse levels of interparental adversity and child vulnerabilities. Consistent with this goal, families were socioeconomically and demographically representative of the counties from which they were drawn. Median family income of the participants fell between $40,000 and $54,000, with 12% of the sample reporting household income below $23,000. A large proportion of the sample was European American (78.6%), followed by smaller percentages of African American (15.2%), Latin American (3.1%), Asian American (1.2%), Native American (0.2%), and other racial (1.7%) families. Families in the study also experienced a relatively wide range of adversity in the family as 33% of mothers and 43% of fathers in our sample could be classified as maritally dissatisfied based on scores below 100 on the Short Marital Adjustment Test (SMAT), with 53% of the couples containing at least one maritally dissatisfied partner (e.g., SMAT; Locke & Wallace, 1959). Further illustrating the occurrence of risk factors in our sample, proportions of children who scored in the clinical range ($t \geq 60$) on parent Child Behavior Checklist reports of internalizing and externalizing symptoms averaged 21% and 18%, respectively, a percentage that is modestly higher than a representative sample of U.S. children (Achenbach, 1991).

Procedures

Families visited the laboratories each year for two visits which were spaced one week apart. During the first visit at Wave 1, mothers, fathers, and the target child participated in a triadic interaction task in which members were instructed to play Jenga, an interactive game, for 15 min. The task was structured to elicit family involvement, competition, and interest. In addition, mothers and fathers participated in an interparental interaction task in which they were asked to manage and resolve two topics that resulted in common, but intense interparental disagreements (see Du Rocher Schudlich, Papp, & Cummings, 2004). Finally, assessments of dyadic parent–child relationships were obtained from separate 10-min play and cleanup tasks during the Wave 1 visit. The task consisted of 5 min of free play between the parent and child followed by a 5-min period in which the parent attempted to have the child clean up the toys. Fathers participated at the end of the first visit, while the mothers participated in the task at the end of the second visit. Videotaped records of these interactions were obtained for later coding of behaviors. Children's classroom teachers independently completed questionnaires at Waves 1, 2, and 3, spaced 1 year apart, to assess children's socioemotional adjustment in the school context.

Measures

Interparental relationship (Wave 1). Interaction behaviors of mothers and fathers during the interparental discussion tasks during the Wave 1 visit were evaluated using subscales from the System for Coding Interactions in Dyads (SCID; Malik & Lindahl, 1996). Molar ratings were yielded for each of the two interparental interactions on 5-point continuous scales ranging from 1 (*very low*) to 5 (*high*). These scales have been widely used across various populations with demonstrated reliability and validity in relation to similar interparental interaction measures (Malik & Lindahl, 1996).

Maternal and paternal hostility during each of the interparental interactions were assessed using the following SCID scales: (a) Verbal Aggression, which is defined as the level of hostile and aggressive behaviors and verbalizations each partner expresses toward the other, and (b) Negativity and Conflict, which reflects spousal displays of anger, frustration, and tension. Intraclass correlation coefficients, which indexed the reliability of two independent coders for 25% of the interactions, ranged from .84 to .97 for mothers and fathers across each of the interactions. Husband and wife behaviors across the two interactions were then summed to create one score for each of the three behaviors reflecting the degree to which each couple used a specific strategy. Coders also rated each couple as a whole using the Negative Escalation code from the SCID, which assesses tendencies of the partners to reciprocate and escalate displays of negative affect and hostility. The intraclass correlation coefficients, which reflect the interrater reliability of two independent coders for 25% of the interactions, were .96 and .97 across the two interactions. Principal components analysis of the individual and couple ratings indicated a single factor, accounting for 91% of the variance in scores. In addition, internal consistency in this sample was .79 for the ratings. Thus, scales were aggregated to form an interparental hostility composite score.

Consistent with the interparental hostility measurement battery, mother, father, and couple withdrawal during the interparental interactions were assessed using SCID scales (Malik & Lindahl, 1996). Maternal and paternal withdrawal were specifically assessed through the SCID Withdrawal scale, with higher scores reflecting displays of repeated, prolonged, and tense forms of detachment and avoidance during the interparental interactions. Intraclass correlation coefficients, which index interrater reliability, ranged from .85 to .96 for mothers and fathers across each of the two interactions. To obtain a third index of withdrawal, coders rated the couple as a whole using the Pursuit/Withdraw Scale from the SCID, which assesses the extent to which one partner attempts to avoid discussion while the other partner attempts to attempts to continue the discussion. The intraclass correlation coefficients indexing interrater reliability for the couple were .90 and .91 across the two interactions. Principal components analysis of the individual and couple ratings indicated a single factor, accounting for 90% of the variance in scores. In addition, internal consistency in this sample was .76 for the ratings. Thus, scales were aggregated to form an interparental withdrawal composite score.

Parent–child relationship (Wave 1). Interactions between mother–child and father–child dyads and were assessed during the play and cleanup tasks at Wave 1 using a global rating scale assessing the frequency, quality, and intensity of behaviors on a 9-point scale, ranging from 1 (*not at all characteristic*) to 9 (*mainly characteristic*).

Parent behaviors were evaluated using subscales from the Iowa Family Interaction Rating Scales (IFIRS; Melby & Conger, 2001). The widely used IFIRS has demonstrated validity and reliability across studies (see Melby & Conger, 2001). Coders, who were blind to ratings of the interparental and triadic interactions, independently rated mother and father parenting behaviors. Parental emotional availability during the parent–child interaction task was assessed by the Warmth/Support, Positive Reinforcement, and Neglecting/Distancing scales of the IFIRS. The Neglecting/Distancing scale measures parental indifference, apathy, and unresponsiveness during the parent–child interactions, whereas Warmth/Support is characterized by displays of affection and support toward the child. Finally, Positive Teinforcement reflects positive parental responses (e.g., praise, approval, rewards) to appropriate or exemplary child behavior. Separate ratings of the codes were obtained during play and compliance components of the interaction task. Intraclass correlation coefficients, which reflected interrater reliability among two coders for 21% of the interactions, ranged from .91 and .94 for ratings of the parenting codes for mothers and fathers. Principal components analysis of mother and father ratings indicated a single factor, accounting for 64% of the variance in scores, while the internal consistency coefficient in this sample was .83. Thus, ratings were aggregated to form a single emotional availability score (the Neglecting/Distancing scales were reverse coded prior to compositing).

Parental intrusiveness was assessed with the Intrusiveness subscale of the IFIRS system, measuring intrusive and overcontrolling behaviors by the parents. In structured tasks, this behavior may be manifested by extreme concern about completing the task, constriction of the child's autonomy and hindering the child from exploring and setting the pace for the task. Intraclass correlation coefficients ranged from .82 and .88 for mothers' and fathers' ratings, respectively. Principal components analysis of mother and father ratings indicated a single factor, accounting for 53% of the variance in scores, and internal consistency in this sample was .71. Thus, ratings were composited to form a single intrusiveness score.

Child behaviors were evaluated using the Relatedness scale that is designed to assess children's comfort and positive affect in parent–child interactions (Davies, 2002). The Relatedness subscale captures the degree to which a child's interest in initiating and maintaining pleasurable and harmonious interactions with the parent as a means of promoting positive affect and well-being in the dyad. Ratings on the 5-point scale take into account the number of attempts by the child to engage the parent, the duration of the attempts, and the quality of the accompanying affect. Whereas low scores reflects children's attempts to engage the parent that are brief, mild, and relatively superficial or ambiguous in intent, higher scores are characterized by repeated, socially skilled, prolonged, and enthusiastic attempts to initiate or maintain positive relations with the parent. Intraclass correlation coefficients for interrater reliability ranged from .70 to .84 for children's ratings with mothers and fathers ratings, respectively. Principal components analysis of ratings for children across tasks indicated a single factor, accounting for 84% of the variance in scores, and internal consistency in this sample was .83. Thus, ratings were composited to form a single relatedness score.

Mother–father–child relationship (Wave 1). Family-level behavior was evaluated using constructs from the Coparenting and Family Rating system (CFRS; McHale, Keursten-Hogan, & Lauretti, 2001) and the System for Coding Interactions and Family Functioning (SCIFF; Lindahl & Malik, 1996). The global rating scales of these systems were coded on a 5-point scale, ranging from 1 (*very low*) to 5 (*excessive*). Specifically, in order to index coparenting difficulties in the presence of the child, the Competition and Cooperation subscales from the CFRS were utilized. The Competition subscale captures active parental intrusiveness and interference in the other parent's child-directed activities, while the Cooperation subscale measures the ability of coparents to work as a team and support one another in family interactions. Finally, the Cohesiveness subscale of the SCIFF was utilized to index the sense of unity, togetherness, and closeness within the triad. Intraclass correlation coefficients, which reflected interrater reliability among two coders for 25% of the interactions, ranged from .60 to .73 at Wave 1 across the three scales.

Child internalizing and externalizing symptoms (Waves 1, 2, and 3). Internalizing and externalizing symptoms were assessed using their respective broadband scores from the Teacher Report Form (Achenbach, 1991). For each item, teachers indicated whether or not each statement is true of the child on a 3-point ordinal scale, ranging from 0 (*not true*) to 2 (*very true*). Broadband scores for internalizing symptoms included the Withdrawn/Depressed, Somatic Complaints, and Anxious/Depressed subscales. Internal consistencies for internalizing scores across the three waves ranged from .83 to .90. Broadband externalizing symptoms were based on the Aggression and Delinquent subscales. Internal consistencies for the broadband externalizing score across the three waves ranged from .92 to .95.

Children's difficulties in classroom engagement (Waves 1, 2, and 3). To obtain an assessment of children's difficulties with engagement in the classroom, two scales were used. First, teacher report on the Hyperactivity/Distractibility subscale of the Child Behavior Scale (CBS) was used as a measure of children's behavior at school (Ladd & Profilet, 1996). The subscale consists of four items (e.g., ''poor concentration, attention span'') rated along a 3-point scale ranging from 1 (*doesn't apply*) to 3 (*certainly applies*). Internal consistency in this sample ranged from .84 to .87 across the different time points. Prior research has supported the validity of the CBS (Ladd & Profilet, 1996). Second, teachers reported on the Cooperative Participation subscale from the Teacher Rating Scale of School Adjustment (TRSSA; Birch & Ladd, 1997). The subscale consists of seven statements assessing teacher appraisals of children's participation in the classroom (e.g., ''follows teacher's directions'' and ''accepts responsibly for a given task'') on a 3-point scale from 1 (*doesn't apply*) to 3 (*certainly applies*). The scale was later reversed such that higher scores reflected lower levels of cooperative participation. The TRSSA has demonstrated reliability as well as content and construct validity (Birch & Ladd, 1997). Internal consistency across the three waves ranged from .76 to .90. To create an overall Children's Classroom Difficulties scale for each time point, the two subscales were summed to create a combined score. Internal consistency of the overall composite exceeded .85 at each time point.

Children's difficulties in emotional adjustment to school (Waves 1, 2, and 3). To obtain an assessment of children's difficulties in emotional adjustment to school we followed previous conceptualizations of poor emotional adjustment in the school as reflecting children's experiences of loneliness, disengagement, and difficulties with peers in the school context (e.g., Buhs & Ladd, 2001). Three subscales, rated on a 3-point scale from 1 (*doesn't apply*) to 3 (*certainly applies*), were used to assess this construct. First, the School Avoidance and School Liking subscales from the TRSSA (Birch & Ladd, 1997) were used. The school avoidance scale consists of five items that assess teacher's perceptions of a child's efforts to avoid the classroom (e.g., ''makes up reasons to go home from school, feigns illness at school''). Internal consistencies in this sample were .70 at Time 1, .77 at Time 2, and .83 at Time 3. Second, the School Liking subscale is a five-item index of teacher's perceptions of how much a child likes being in school (e.g., ''likes to come to school, has fun at school''). Internal consistencies in this sample were .86 at Time 1, .86 at Time 2, and .88 at Time 3. This scale was reverse coded. To obtain an assessment of children's ability to connect with peers in school, teacher report on the Prosocial Behavior subscale of the CBS was used (Ladd & Profilet, 1996). This scale assesses children's tendencies to be empathic, cooperative, and self-sacrificing with peers and was measured with items that referred to behaviors such as helping, concern, and kindness. Internal consistency in this sample ranged from .81 to .93 across the different time points. Items were reverse coded such that higher scores reflect poorer functioning with peers. To create an overall Children's Emotional Adjustment Difficulties scale for each time point, the three subscales were summed to create a combined score. Internal consistency of the overall composite exceeded .81 at each time point.

Results

The results are presented in two sections. The first details the results of the latent class analysis of the family interaction constructs and the second presents latent growth curve (LGC) analyses of children's adjustment trajectories in the school context as a function of family group. All models were estimated using the latent variable software Mplus, Version 5.1 (Muthén & Muthén, 2006).

Examination of Family Typology at Wave 1

Latent Profile Analysis (LPA; e.g., Hagenaars & McCutcheon, 2002), was utilized to determine family profiles. LPA is a variant of latent class analysis techniques and is used when manifest indicators of the categorical latent variable are on a continuous scale as family assessments were in the present study. As in other latent variable modeling techniques, the profiles in LPA are not observable directly from the data but are identified based on a function of a set of the continuous manifest indicators. To determine the optimal number of profiles, we used two likelihood tests for comparing nested models including the Bayesian information criterion (BIC; Schwartz, 1978) and the Vuong–Lo–Mendell–Rubin likelihood ratio test (VLMR; Lo, Mendell, & Rubin, 2001). The model with the lowest BIC value is generally considered the best-fitting model. As a further test of model fit, the VLMR provides a p value that indicates whether the k-1 profile model is rejected in favor of the k profile model (see Nylund, Asparouhov, & Muthen, 2007, for more details). Finally, it is also important to consider the practical applications of profile solutions along with statistical measures of model fit. Therefore, substantive implications were also taken into account when determining optimal number of profiles (e.g., Muthén, 2004). Furthermore, for each family, the LPA analysis produces posterior (Bayesian) probabilities of likelihood of membership in each latent profile, and families are classified into the latent profile for which the posterior probability is highest. The probabilities are a function of the model's parameters (estimated conditional response probabilities and estimated prevalence of each latent class). Inspection of these classifications and posterior probabilities is necessary to ensure that families have a high likelihood of being classified correctly. Finally, the latent profile variable indicators (e.g., interparental withdrawal, interparental hostility, parental warmth, parental intrusiveness) were each standardized to aid in interpretation of the latent profiles.

To examine the best profile solution, we extracted two, three, and four latent profiles from our models. Results of the LPA revealed that model fit was best for the three-profile model (BIC = 5897.54; VLMR 2 vs. 3 model = 108.61, $p < .05$), relative to the two (BIC = 5953.89; VLMR 1 vs. 2 model = 163.56, $p < .05$) and four (BIC = 5889.39; VLMR 3 vs. 4 model = 61.88, $p = .49$, *ns*) profile models. Thus, while the difference in BIC values between the three-profile and four-profile models was positive ($\Delta = 8.15$), the VLMR indicated that the three-profile solution was a significantly better fit than a two-profile solution, and the VLMR indicated that the four-profile solution did not provide a statistically improved fit relative to the three-profile solution. Therefore, the three-profile solution is regarded as a statistically comparable but more parsimonious model than the four-profile solution. In terms of substantive considerations, the three-profile solution cohered into cohesive, disengaged, and enmeshed patterns among indicator variables. Although the four-group solution contained the three profiles as culled in the three-group solution, it contained one profile with only four families that evidenced high levels of interparental hostility, moderate levels of parental emotional availability and intrusiveness, and low levels of withdrawal. Accordingly, this small group of families closely resembled the profile of an enmeshed pattern identified in the three-profile solution. Given the results from the VLMR, conceptual overlap of the profiles between the three- and four-profile solutions, as well as the extremely small sample size in the fourth profile, we retained the three-profile solution.

Table 1 displays the probabilities of the three-profile LPA model and reveals the degree of fit among the profiles for the families in the study. In the present study, average latent class probabilities for most likely latent class membership by latent class were excellent. Specifically, families who were profiled as disengaged had a 90.6% average probability of fitting the disengaged profile, a 6.5% probability of fitting the cohesive profile, and a 2.9% probability of fitting the enmeshed profile. Families who were profiled as cohesive had a 95.4% average probability of fitting the cohesive profile, a 1.9% probability of fitting the disengaged profile, and a 2.7% probability of fitting the enmeshed profile.

Table 1
Latent Profile Probabilities for Most Likely Class Membership by Latent Profile Based on Estimated Model

	Latent Profile		
	Disengaged	Cohesive	Enmeshed
Latent profile classification			
Disengaged	90.6%	6.5%	2.9%
Cohesive	1.9%	95.4%	2.7%
Enmeshed	4.5%	4.1%	91.4%

Finally, families who were classified as enmeshed had a 91.4% average probability of fitting the enmeshed profile, a 4.5% probability of fitting the disengaged profile, and a 4.1% probability of fitting the cohesive profile. Inspection of the cases revealed that three families displayed some indiscrimination among profiles. Their highest profile probability (range = .49–.52) coupled with high cross-profile probabilities (range = .42–.45) among the other profiles suggested that they could not be validly classified within one of the three latent profiles (e.g., Nagin, 2005). Therefore, these families were not retained in the analyses.

Table 2 shows the means and standard deviations of the standardized measures of family process for each of the three family profiles identified by the latent profile analyses as well as the results of analysis of variance comparisons among the groups. The first profile displayed low levels of interparental hostility and withdrawal, parental intrusiveness, and family competition as well as high levels of parental emotional availability, child relatedness, and family cooperation and cohesiveness. Based on earlier empirical work and theoretical conceptualizations, these families were classified as exhibiting a cohesive pattern of interactional style within family subgroups. Families in the second profile displayed very high levels of interparental hostility, parental emotional availability and intrusiveness, and family competition along with lower levels of interparental withdrawal, child relatedness, and family cooperation and cohesiveness. Given evidence of high levels of hostility and intrusiveness coupled with modest to moderate levels of warm and supportive parenting, we classified these families as enmeshed. Finally, the third profile of families was classified as displaying disengaged patterns of interaction. These families were characterized by relatively high levels of interparental withdrawal, parental intrusiveness, while also exhibiting low levels of interparental hostility, parental emotional availability, family cooperation, competition and cohesiveness, and child relatedness.

In addition, several family background variables were included in the analyses to examine their relation to family typology membership. Child gender, maternal age, and family income were specified as covariates in our latent profile analyses to incorporate their effects on the odds of model classification into profiles. Using the cohesive profile as the comparison group, two comparisons were made for each covariate: (a) the likelihood of being categorized as an enmeshed family compared to a cohesive family and (b) the likelihood of being

Table 2
Means, Standard Deviations, and ANOVA Comparisons of the Three Family Typologies on Seven Defining Variables

	Cohesive (C; *n* = 137)		Enmeshed (E; *n* = 51)		Disengaged (D; *n* = 43)			
	M	*SD*	*M*	*SD*	*M*	*SD*	*F*(2, 230)	Post hoc
Wave 1								
Interparental hostility	−.46	.53	1.47	.79	−.27	.64	187.50***	E > C, D
Interparental withdrawal	−.36	.67	−.18	.74	1.38	.97	90.50***	D > E, C
Parental emotional availability	.31	.82	.01	1.02	−.99	.86	36.17***	E, C > D
Parental intrusiveness	−.14	.95	.09	1.07	.34	.99	4.20***	D > C

Triadic cooperation	.18	.91	−.16	.98	−.37	1.18	5.97***	C > D, E
Triadic cohesiveness	.27	.95	−.20	.92	−.61	.91	15.59***	C > E, D

Note. Post hoc comparisons used Tukey's HSD to control for alpha level, ">" refers to significantly larger whereas "," refers to not significantly different at alpha = .05 level. ANOVA = analysis of variance.
$^{***}p \leq .001$.

categorized as a disengaged family compared with a cohesive family. Results indicated that only family income had an effect on probability of class membership for disengaged versus cohesive families. The logistic regression coefficient for family income (–.89, $p < .05$) indicated that as family income increased the probability of being classified as disengaged versus cohesive decreased. Other class comparisons were not significant.

Links Between Family Typology and Children's Adjustment Trajectories

Our final set of analyses explored whether children's adjustment trajectories were associated with family typology using Mplus 5.1 statistical software for estimating trajectories for each group (Muthén & Muthén, 2006). Accordingly, unconditional LGC models were specified for each dependent measure (e.g., internalizing symptoms) within each family profile (e.g., cohesive). Unconditional LGC allow for the examination of the existence and significance of average intercepts and slopes within each family profile. Because our analyses involved both categorical (family profile) and continuous (outcome) measures, we utilized the MPlus options for estimating mixture models. First, we examined whether the slope of each family typology was significantly different from zero. Second, we examined whether the slopes of each family typology are significantly different from each other. To accomplish this second goal, we tested for significant differences among the family profiles on model-derived intercepts and slopes. However, because a chi-square test is not provided in mixture models, the chi-square difference test is computed as $2d$ where d is the difference between the log-likelihood values from the two models being compared (McLachlan & Peel, 2000). The difference in degrees of freedom is computed as the difference in the number of parameters.

The LGC model of children's linear externalizing trajectories was examined first. Mean intercept values were positive and significant in each of the three groups ($p < .05$). Log-likelihood comparisons among the different family typologies revealed that children in disengaged families had significantly higher intercept values when compared with children in enmeshed and cohesive families (see Table 3). The means of the slope factors for cohesive, disengaged, and enmeshed families were 0.24 ($p = 0.13$), 1.37 ($p < .05$), and .15 ($p = 0.50$), respectively (see Figure 1). These findings indicated that children's externalizing symptoms in the sample increased across all family profiles; however, the magnitude of the increase was only significant for children from disengaged families. Furthermore, log-likelihood comparisons among the family profiles on linear slope means revealed that children from disengaged families had significantly

accelerated externalizing trajectories in comparison to children from cohesive and enmeshed families. Average slopes for children from disengaged and enmeshed families were no different suggesting similar change over time.

The LGC model of children's linear internalizing trajectories was examined next (see Figure 2). Mean intercept values were positive and significant in each of the three groups ($p < .05$). Log-likelihood comparisons among the different family typologies revealed no significant differences in average intercept values, suggesting that children started at relatively similar levels of internalizing symptoms (see Table 3). Findings also revealed that children from disengaged families had a significant and positive mean slope ($\mu = .74$, $p < .05$), children from enmeshed families had a significant and positive mean slope ($\mu = .55$, $p < .05$), and children from cohesive families had a nonsignificant and positive mean slope ($\mu = .05$, $p = .63$). Furthermore, average slopes for children from disengaged and enmeshed families were no different suggesting similar change over time.

The LGC model of children's linear trajectories of classroom difficulties revealed that while mean intercept values were positive and significant across

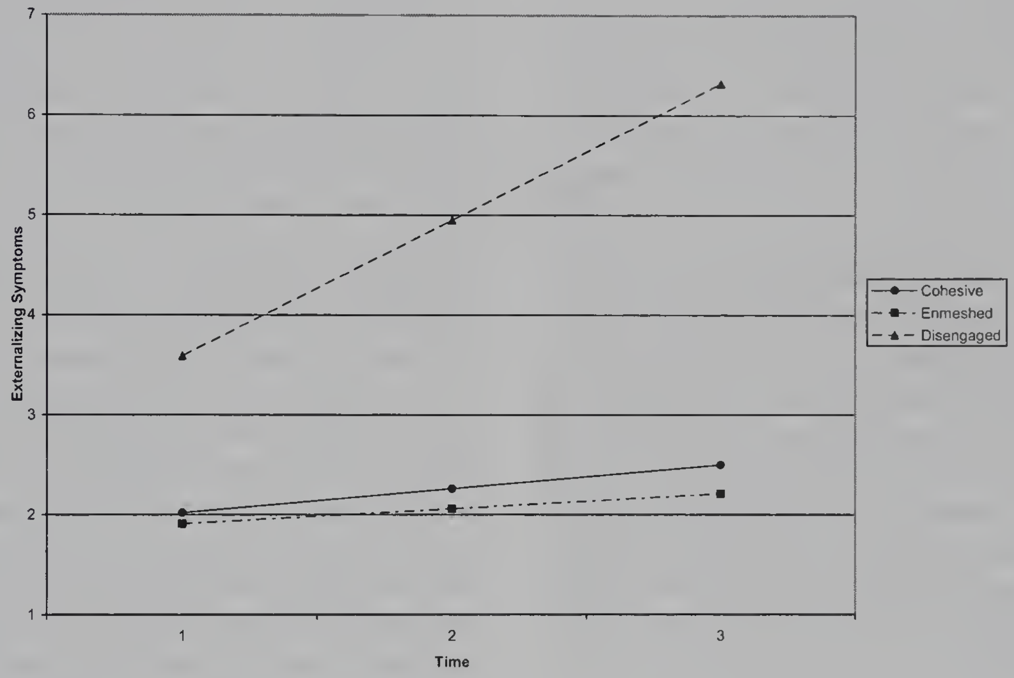

Figure 1. Trajectories for teacher-reported externalizing symptoms.

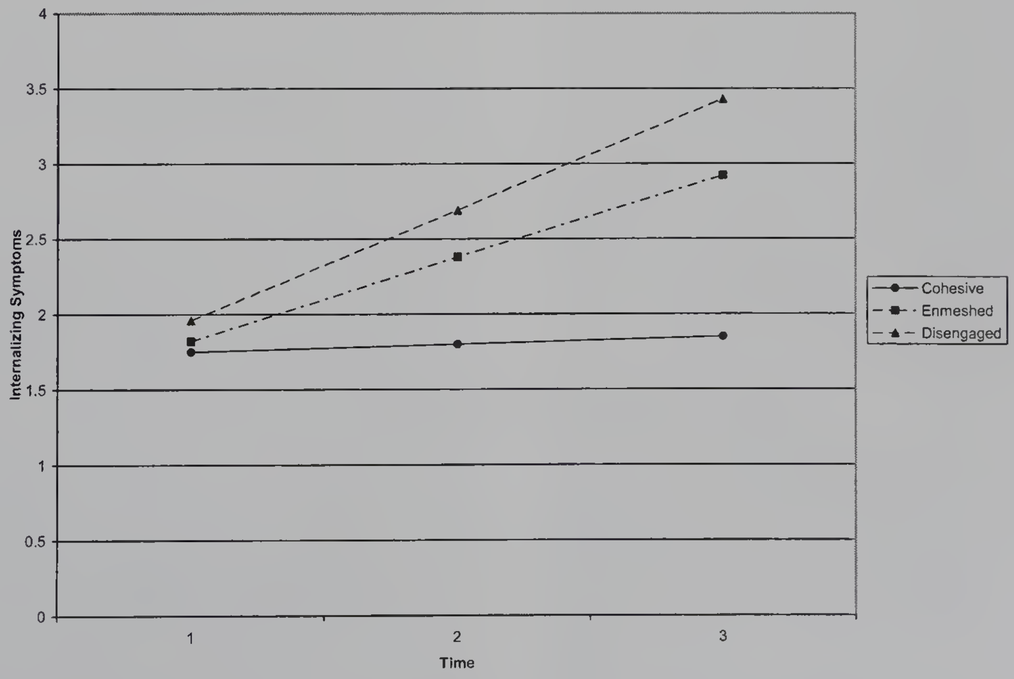

Figure 2. Trajectories for teacher-reported internalizing symptoms.

the three groups, children in disengaged families had significantly higher intercept values when compared to children in enmeshed and cohesive families (see Table 3). Furthermore, children from disengaged families had a significant and positive mean slope ($\mu = .58$, $p < .05$) while children from cohesive ($\mu = .18$, $p = .07$) and enmeshed ($\mu = .22$, $p = .09$) families had nonsignificant slopes (see Figure 3). Log-likelihood comparisons among the means further revealed that children from disengaged families had elevated trajectories of classroom difficulties in comparison to children from enmeshed and cohesive families. No other differences were detected.

Our final analysis examined the LGC model of children's difficulties in emotional adjustment to school. Findings revealed that no differences among the groups on the average intercept values (Table 3); however, children from both disengaged and enmeshed families had significant and positive mean slopes (μs = .57 and .45, respectively, $p < .05$) while children from cohesive families had a nonsignificant slope ($\mu = .03$, $p = .81$). Thus, children from disengaged and enmeshed families experienced significant increases in difficulties with emotional adjustment to school over time. Log-likelihood comparisons among the means further revealed that children from enmeshed and disengaged families had elevated trajectories of classroom emotional difficulties in comparison with children from cohesive families only (see Figure 4). No other differences were detected.

Discussion

The findings of the present study demonstrate the value of utilizing a latent class analysis of family interaction constructs for delineating distinct configurations of relationship and interactional parameters in family systems. In addition, patterns of family interactions had developmental utility, with distinct typologies meaningfully associated with differences in longitudinal trajectories of child adjustment in the school context (e.g., Jacobvitz et al., 2004; Johnson, 2003; Kerig, 1995; McHale et al., 2004). Thus, the present study highlights new avenues for the analysis of family functioning and implications for child development in the school context. From a substantive perspective, the present study adds to our understanding of the developmental implications of different configurations of family functioning proposed in family systems theory. From a methodological perspective, the specific focus of coupling latent class analysis with LGC modeling illuminates a new way of examining complex family systems conceptualizations within a developmental framework.

Consistent with past empirical and clinical work, three specific family typologies could be reliably identified utilizing multilevel assessments of family interactions spanning both dyadic and triadic systems. Solutions extracted a cohesive profile across the interparental, parent–child, and triadic subsystems in accordance with previous classifications of families who effectively maintain relationship

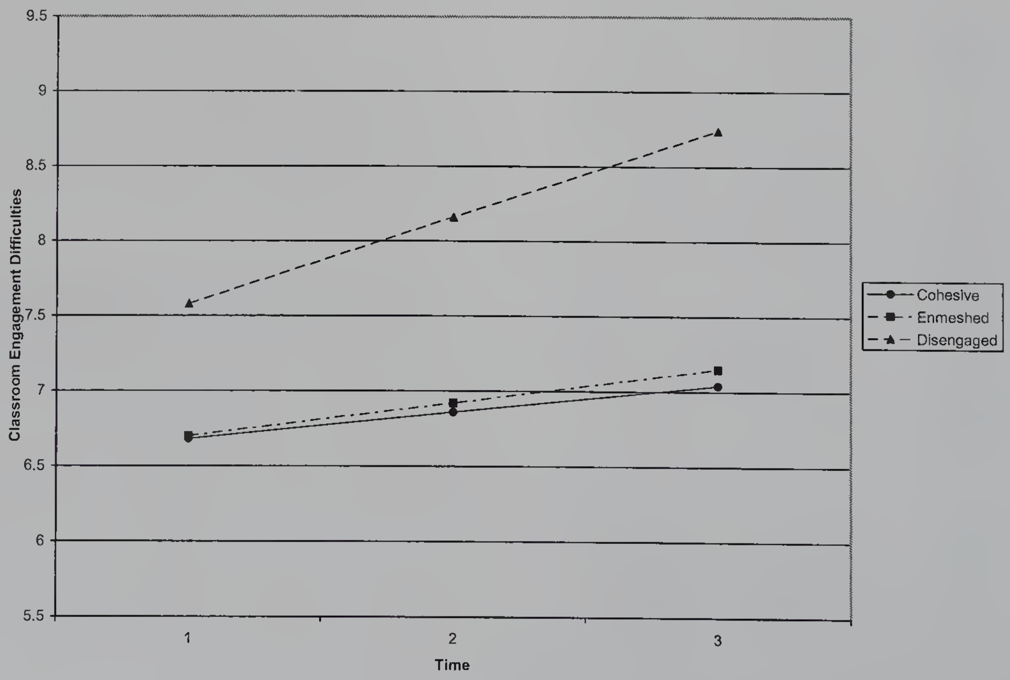

Figure 3. Trajectories for teacher-reported difficulties in classroom engagement.

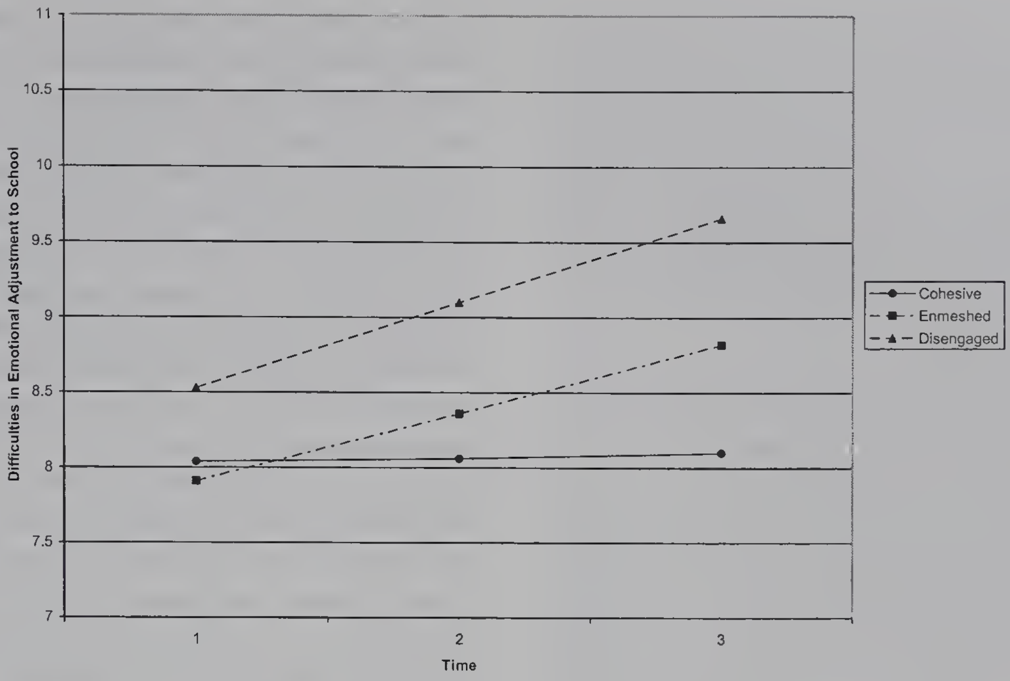

Figure 4. Trajectories for teacher-reported difficulties in emotional adjustment to school.

boundaries by permitting members to access resources without threatening their autonomy (Davies et al., 2004; Kerig, 1995). Families classified as disengaged exhibited low levels of positive affect across family systems along with high levels of diminished engagement and intrusiveness. Enmeshed families evidenced high levels of hostility and negative affect, intrusiveness, and competitiveness; low levels of cohesion; and modest levels of warmth and availability in parent–child relationships. Difficulties in regulating negative affect and maintaining positive affect in the presence of diffuse boundaries map onto previous distinctions in the literature. Thus, this study adds to a growing line of research (e.g., Davies et al., 2004; Johnson, 2003; O'Connor et al., 1998) that advocates for incorporating pattern-based approaches in studying family relationships across multiple family systems.

To address the developmental utility of these specific configurations, we examined how patterns of family functioning were associated in meaningful ways with changes in children's adjustment in the school context. As hypothesized, children in enmeshed families exhibited significantly greater slopes of internalizing symptomatology as well as difficulties navigating emotional adjustment to school than children from cohesive groups. While this pattern of findings requires replication before drawing any definitive conclusions about the developmental timing of enmeshed family processes for children, it does raise some plausible interpretations. First, children who have experienced erosion of family boundaries inherent in enmeshed families may find themselves emotionally drawn into family difficulties, which in turn may amplify worries and distress about family relationships (e.g., Davies et al., 2004). In turn, this preoccupation and concern about family problems may detract from the demands of the school context and result in greater emotional disengagement from school. In addition, highly enmeshed subsystems increase the likelihood of various constellations of relationships within the family that are highly toxic to children's development (e.g., Jacobvitz et al., 2004). For example, enmeshed families may restrict children's autonomy by promoting dysfunctional family roles characterized by parent–child alliances, spousification of children (i.e., the child serves as a primary source of intimacy for the parent), or parentification of children (i.e., the child serves as a caregiver to the parent; Kerig, 1995; Sroufe, Jacobvitz, Mangelsdorf, DeAngelo, & Ward, 1985). Thus, increased exposure to interparental negative affect, integration into inappropriate family constellations, and lowered autonomy may undermine children's successful adaptation in extrafamilial settings such as the school context.

Moreover, given that children from enmeshed families were comparable to cohesive children in their initial levels of internalizing symptoms, it appears that the early elementary school years may be a sensitive period for the role of enmeshed family processes in the development of internalizing difficulties (e.g., Cicchetti & Toth, 1998). Children's adaptation to school is associated with significant cognitive changes including growing abilities for abstract representations and reasoning ability as well as developmental shifts in the complexity of self-cognitions, with a significant transition occurring in the 7- to 8-year-old range (e.g., Harter, 1983). In turn, these advancing abilities over the early school years may potentiate children's vulnerability to internalizing symptoms when experiencing family enmeshment.

Consistent with previous studies examining links between disengaged family patterns and children's externalizing behaviors (e.g., Davies et al., 2004; Kerig, 1995), the present study found that disengaged family patterns were associated with higher initial values on externalizing symptomatology and difficulties in classroom engagement. In addition, examination of slope trajectories was also consistent with prior empirical work in the sense that children from disengaged families had significantly greater slopes for classroom engagement difficulties and externalizing problems relative to both cohesive and enmeshed family profiles. Thus, in the case of disengaged families, it may be that the family's failure to fulfill the responsibility of providing support, resources, and protection results in children's difficulties in regulating behavior in the school context. In attempting to understand the mechanisms by which these associations occur, it may be that it is adaptive for children to dismiss or downplay the value of interpersonal relationships when confronted with fragmented and emotionally detached interaction patterns in the family (e.g., Minuchin, 1974). Unfortunately, when these responses are exhibited within the context of the school, a maladaptive pattern may result, including greater use of aggressive and inappropriate behaviors, greater alienation from teachers, and greater inability to attend to and adhere to rules and regulations for school functioning.

Finally, an intriguing finding arising in the present study was that children in disengaged families were comparable to children in enmeshed families in exhibiting a heightened vulnerability to internalizing symptoms and difficulties in emotional adjustment to school. In the context of the prevailing notion that the rigid boundaries and emotional distance characteristic of disengaged families is a more potent prognosticator of externalizing difficulties, these findings may be somewhat surprising. However, these results are consistent with an emerging body of literature proposing cascading models in development. First, cascade models of family dynamics (e.g., Christensen & Heavey, 1990; Sturge-Apple et al., 2006) suggest that disengaged family processes may be particularly pathogenic mechanisms that might not only engender alienation and disenfranchisement in family members but may also promote significant doubts and worries in children about the ability of the family to serve as a source of protection in the face of external demands. Thus, the barren emotional climate present in a disengaged family network may amplify adaptive difficulties across several domains of functioning. In line with this prediction, developmental cascade models (e.g., Masten et al., 2005) theorize that a constellation of difficulties across domains may largely be the function of early occurring externalizing problems in school children. Specifically, the cascade model proposes that externalizing symptoms evoke negative responses by peers and school staff, which in turn sets in motion a cascade of processes that increase children's internalizing symptoms and school problems. The presence of significantly higher initial levels of externalizing and classroom engagement difficulties in children in disengaged families in the current study coupled with the significant changes in internalizing and emotional adjustment domains over time is in accordance with the progressive, transactional effects proposed by Masten et al. (2005).

Several limitations and future directions warrant discussion. First, the relatively short time period utilized limits our generalizability of the developmental trajectories identified. Future work incorporating longer assessment windows may shed additional light on the implications of these family typologies for children's adjustment over time. Second, future research should complement the longitudinal assessment of adjustment problems in the present study with comparable prospective assessment of family typologies to examine how stability and change in family typologies correspond with trajectories of adjustment over time. Third, our models in the present study did not incorporate children's coping in stressful family systems and might have served to further elucidate the links between family typologies and their adjustment. Fourth, minimal differences were found on average intercepts of children's internalizing symptoms as well as emotional adjustment to school. Given that the impact of family patterns on children's adjustment in the school context may take some time to evolve, particularly with respect to internalizing and emotional domains, the lack of differences in the intercept is not surprising. However, because this is one of the first articles to chart these relations during this developmental period, we exercise caution in interpreting these null findings. Finally, results are based on a community sample; the function, correlates, and sequelae of family configurations in high risk and clinical populations may be different from those reported here.

In summary, our results suggest that employing pattern-based approaches to family functioning and child development may advance our understanding of the developmental sequelae of children's adaptation within different typologies of family functioning. Consistent with models of developmental psychopathology, maladaptive family patterns may potentiate children's trajectories of adjustment difficulties during the early school years. However, the findings here suggest that future research should consider multiple domains of adaptation simultaneously in order to fully explore how family functioning impacts children across an array of adjustment outcomes. At a broader level, this study also has implications for the utility of broadening transactional approaches to children's development in extrafamilial contexts as a function of different interactional patterns within the family system. Thus, delineating the interplay between family relationships may further advance understanding of child vulnerability and resilience within extrafamilial contexts.

Toddlers' Prosocial Behavior: From Instrumental to Empathic to Altruistic Helping, Margarita Svetlova, Sara R. Nichols, and Celia A. Brownell.

A Large-Scale Evaluation of the KiVa Anti-Bullying Program, Antti Kärnä, Marinus Voeten, Elisa Poskiparta, Todd D. Little, Anne Kaljonen, and Christina Salmivalli.

Movement Planning Reflects Skill Level and Age Changes in Toddlers, Yu-ping Chen, Rachel Keen, Kerstin Rosander, and Claes von Hofsten.

Young Children Selectively Avoid Helping People With Harmful Intentions, Amrisha Vaish, Malinda Carpenter, and Michael Tomasello.

Danish Majority Children's Reasoning About Exclusion Based on Gender and Ethnicity, Signe Juhl Moller and Harriet Tenenbaum.

How Does It Look? Level 2 Perspective-Taking at 36 Months of Age, Henrike Moll and Andrew Meltzoff.

Emotion Discourse, Social Cognition, and Social Skills in Children With and Without Developmental Delays, Rachel M. Fenning, Bruce L. Baker, and Jaana Juvonen.

A Monozygotic Twin Differences Study of Friends' Aggression and Children's Adjustment Problems, Frank Vitaro, Mara Brendgen, Michel

Boivin, Stephane Cantin, Ginette Dionne, Richard E. Tremblay, Alain Girard, and Daniel Perusse.

Gender Differences in Adolescents' Daily Interpersonal Events and Well-Being, Lisa Flook.

Teacher–Child Relationships and the Development of Academic and Behavioral Skills During Elementary School: A Within- and Between-Child Analysis, Carolina Maldonado-Carreño and Elizabeth Votruba-Drzal.

The Effects of the Fast Track Preventive Intervention on the Development of Conduct Disorder Across Childhood, Conduct Problems Prevention Research Group.

Object Similarity Bootstraps Young Children to Action-Based Verb Extensions, Etsuko Haryu, Mutsumi Imai, and Hiroyuki Okada.

The Impact of Enhancing Students' Social and Emotional Learning: A Meta-Analysis of School-Based Universal Interventions, Joseph Durlak, Roger Weissberg, Allison Dymnicki, Rebecca Taylor, and Kriston Schellinger.

Science Does Not Speak for Itself: Translating Child Development Research for the Public and Its Policy Makers, Jack Shonkoff and Susan Nall Bales.

Domain General Constraints on Statistical Learning, Erik Thiessen.

Reciprocal Relations Between Parenting and Adjustment in a Sample of Juvenile Offenders, Lela Rankin Williams and Laurence Steinberg.

A Randomized Controlled Trial of Child FIRST: A Comprehensive Home-Based Intervention Translating Research Into Early Childhood Practice, Darcy I. Lowell, Alice S. Carter, Leandra Godoy, Belinda Paulicin, and Margaret J. Briggs-Gowan.

Paths of Effects From Preschool to Adult Well-Being: A Confirmatory Analysis of the Child–Parent Center Program, Arthur Reynolds and Suh-Ruu Ou.

Age 26 Cost–Benefit Analysis of the Child–Parent Center Early Education Program, Arthur Reynolds, Judy Temple, Barry White, Suh-Ruu Ou, and Dylan Robertson.

Latino Adolescents' Experiences of Discrimination Across the First Two Years of High School: Correlates and Influences on Educational Outcomes, Aprile Benner and Sandra Graham.

The Generic/Non-Generic Distinction Influences How Children Interpret New Information About Social Others, Andrei Cimpian and Ellen M. Markman.

Two-Year Impacts of a Universal School-Based Social-Emotional and Literacy Intervention: An Experiment in Translational Developmental Research, Stephanie Jones, Joshua Brown, and J. Lawrence Aber.

Conditional Reasoning With False Premises Facilitates the Transition Between Familiar and Abstract Reasoning, Henry Markovits and Hugues Lortie Forgues.

When Easy Comes Hard: The Development of Adaptive Strategy Selection, Rui Mata, Bettina von Helversen, and Joerg Rieskmap.

Coherent Motion Sensitivity and Reading Development in the Transition from Pre-Reading to Reading Stage, Bart Boets, Maaike Vandermosten, Piers Cornelissen, Jan Wouters, and Pol Ghesquière.

Same-Ethnic Friendship Preferences Among German and Turkish Preadolescents Attending Ethnically Heterogeneous Schools, Philipp Jugert, Peter Noack, and Adam Rutland.

Holistic Face Processing in Newborns, 3-Month-Old Infants, and Adults: Evidence From the Composite Face Effect, Chiara Turati, Elisa Di Giorgio, Lara Bardi, and Francesca Simion.

Math-Gender Stereotypes in Elementary School Children, Dario Cvencek, Andrew N. Meltzoff, and Anthony G. Greenwald.

Reporter Discrepancies Among Parents, Adolescents, and Peers: Adolescent Attachment and Informant Depressive Symptoms as Explanatory Factors, Katherine B. Ehrlich, Jude Cassidy, and Matthew J. Dykas.

Urban and Rural Chinese Adolescents' Judgments and Reasoning About Personal and Group Jurisdiction, Charles Helwig, Shaogang Yang, Dingliang Tan, Chunqiong Liu, and Tiffany Shao.

Childhood Trauma and Psychiatric Disorders as Correlates of School Dropout in a National Sample of Young Adults, Michelle V. Porche, Lisa R. Fortuna, Julia Lin, and Margarita Alegria.

The Role of Peer Relationships in the Development of Early School-Age Externalizing Problems, Cristina Sturaro, Pol A. C. van Lier, Pim Cuijpers, and Hans M. Koot.

Relationship Between Language Experiences in Preschool Classrooms and Children's Kindergarten and Fourth-Grade Language and Reading Abilities, David K. Dickinson and Michelle V. Porche.

Intergenerational Transmission of Adaptive Functioning: A Test of the Interactionist Model of SES and Human Development, Thomas Schofield, Monica Martin, Katherine Conger, Brent Donnellan, Tricia Neppl, and Rand Conger.

Mentoring in Schools: An Impact Study of Big Brothers Big Sisters School-Based Mentoring, Carla Herrera, Jean Baldwin Grossman, Tina J. Kauh, and Jennifer McMaken.

Remission of Depression in Parents: Links to Healthy Functioning in Their Children, Judy Garber, Jeffrey A. Ciesla, Elizabeth McCauley, Guy Diamond, and Kelly A. Schloredt.

Double Jeopardy: Poorer Social-Emotional Outcomes for Children in the NICHD SECCYD Experiencing Home and Child Care Environments That Confer Risk, Sarah Watamura, Deborah Phillips, Taryn Morrissey, Kathleen McCartney, and Kristen Bub.

Imagining a Way Out of the Gravity Bias: Preschoolers Can Visualize the Solution to a Spatial Problem, Amy Joh, Vikram Jaswal, and Rachel Keen.

Sequential Progressions in a Theory of Mind Scale: Longitudinal Perspectives, Henry Wellman, Fuxi Fang, and Candida Peterson.

Can Maltreated Children Inhibit True and False Memories for Emotional Information? Mark Howe, Sheree Toth, and Dante Cicchetti.

Parents' Involvement in Children's Learning in the United States and China: Implications for Children's Academic and Emotional Adjustment, Cecilia Cheung and Eva Pomerantz.

Four Children and One Toy: Chinese and Canadian Children Faced With Potential Conflict Over a Limited Resource, Doran French, Xinin Chen, Janet Chung, Miao Li, Dan Li, Huichang Chen, and Li Wang.

Influence of Eye Gaze on Spoken Word Processing: An ERP Study With Infants, Eugenio Parise, Andrea Handl, Letizia Palumbo, and Angela Friederici.

Infant and Maternal Sensitivity to Interpersonal Timing, Anne Henning and Tricia Striano.

Emotion Regulation Profiles, Temperament, and Adjustment Problems in Preadolescents, Maureen Zalewski, Liliana J. Lengua, Anna C. Wilson, Anika Trancik, and Alissa Bazinet.

Developmental Pathways to Integrated Social Skills: The Roles of Parenting and Early Intervention in Raising Healthy Children, Catherine Ayoub, Claire Vallotton, and Ann Mastergeorge.

Consequences of ''Minimal'' Group Affiliations in Children, Yarrow Dunham, Andrew Baron, and Susan Carey.

Revisiting the Impact of Part-Time Work on Adolescent Adjustment: Distinguishing Between Selection, Kathryn C. Monahan, Joanna Lee, and Laurence Steinberg.

Parents as Moderators of the Impact of School Norms and Peer Influences on Aggression in Middle School Students, Albert Farrell, David B. Henry, Sally Mays, and Michael E. Schoeny.

The ABCs of Family Mealtimes: Observational Lessons for Promoting Healthy Outcomes for Children With Persistent Asthma, Barbara Fiese, Marcia A. Winter, and Joanna Corra Botti.

Language Development in Internationally Adopted Children: A Special Case of Early Second Language Learning, Karine Gauthier and Fred Genesee.

Third-Party Social Interaction and Word Learning From Video, Kate O'Doherty, Georgene L. Troseth, Priya Shimpi, Elizabeth Goldenberg, Nameera Akhtar, and Megan M. Saylor.

Computer-Assisted Remedial Reading Intervention for School Beginners at Risk for Reading Disability, Nina Saine, Marja-Kristiina Lerkkanen, Timo Ahonen, Asko Tolvanen, and Heikki Lyytinen.

Desire for Increased Autonomy and Adolescents' Perceptions of Peer Autonomy: ''Everyone Else Can; Why Can't I?'' Christopher Daddis.

Almost Thinking Counterfactually: Children's Understanding of Close Counterfactuals, Sarah Beck and Carlie Guthrie.

CSRP's Impact on Low-Income Preschoolers' Pre-Academic Skills: Self-Regulation as a Mediating Mechanism, C. Cybele Raver, Stephanie

M. Jones, Christine Li-Grining, Fuhua Zhai, Kristen Bub, and Emily Pressler.

Does God Make It Real? Children's Belief in Religious Stories From the Judeo-Christian Tradition, Victoria Cox Vaden and Jacqueline D. Woolley.

Changes in Early Adolescents' Sense of Responsibility to Their Parents in the United States and China: Implications for Their Academic Functioning, Eva Pomerantz, Lili Qin, Qian Wang, and Huichang Chen.

Two- to Eight-Month-Old Infants' Perception of Dynamic Auditory-Visual Spatial Co-Location, Gavin Bremner, Alan Slater, Scott Johnson, Uschi Mason, Jo Spring, and Maggie Bremner.

Longitudinal Associations Between Marital Instability and Child Sleep Problems Across Infancy and Toddlerhood in Adoptive Families, Anne Mannering, Gordon Harold, Leslie Leve, Katherine Shelton, Daniel Shaw, Rand Conger, Jenae Neiderhiser, Laura Scaramella, and David Reiss.

Promoting Effective Parenting Practices and Preventing Child Behavior Problems in School, Laurie Brotman, Esther Calzada, Keng-Yen Huang, Sharon Kingston, Spring Dawson-McClure, Dimitra Kamboukos, Amanda Rosenfelt, Ami Schwab, and Eva Petkova.

Infantile Amnesia Across the Years: A 2-Year Follow-Up of Children's Earliest Memories, Carole Peterson, Kelly L. Warren, and Megan M. Short.

Hemoglobin, Growth, and Attention of Infants in Southern Ethiopia, Nicki Aubuchon-Endsley, Stephanie L. Grant, Getenesh Berhanu, David G. Thomas, Sarah Schrader, Devon Eldridge, Tay S. Kennedy, and Michael Hambidge.

Transition From Crawling to Walking and Infants' Actions With Objects and People, Lana Karasik, Catherine Tamis-LeMonda, and Karen Adolph.

The Genetic and Environmental Covariation Among Psychopathic Personality Traits and Reactive and Proactive Aggression in Childhood, Serena Bezdjian, Catherine Tuvblad, Adrian Raine, and Laura A. Baker.

fellowships available

The Radcliffe Institute for Advanced Study at Harvard University awards 40 funded residential fellowships each year designed to support scholars, scientists, artists, and writers of exceptional promise and demonstrated accomplishment.

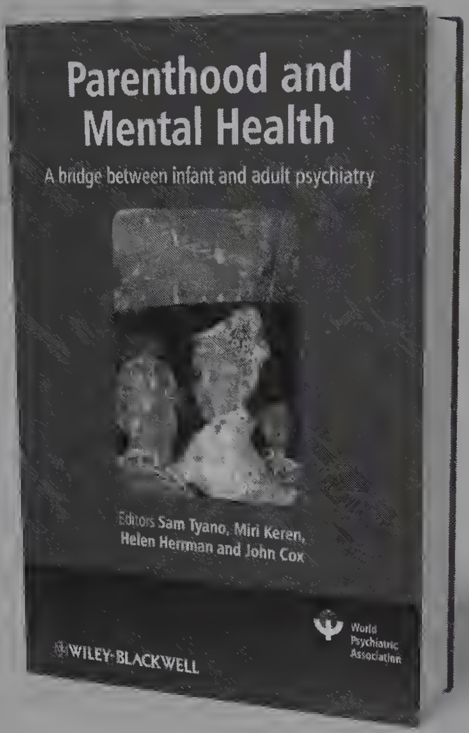
Parenthood and Mental Health
A bridge between infant and adult psychiatry

EDITED BY

Sam Tyano, Tel Aviv University, Sackler School of Medicine, Israel
Miri Keren, Geha Mental Health Center, Petach Tikva, Israel
Helen Herrman, University of Melbourne, Australia
John Cox, University of Gloucestershire, UK



Parenthood and Mental Health
A bridge between infant and adult psychiatry
Editors Sam Tyano, Miri Keren, Helen Herrman and John Cox
WILEY-BLACKWELL
World Psychiatric Association

Across all cultures parenting is the foundation of family life. It is the domain where adult mental health meets infant development. Beginning in pregnancy, parenting involves many conscious and unconscious processes which have recently been shown to affect a child's development significantly. This book focuses on pregnancy and the first year of life, providing a thorough account of the points of encounter between adult and infant psychiatry. In a fresh and comprehensive way, it summarises knowledge about early parenting, including a critical analysis of parenting, what it means to be a "good enough parent", and its relationship to infant, parent and family outcomes. In addition to the psychiatric dimension, the book emphasises the biological aspects of parenting, parental psychopathology and normal and abnormal infant development.

Hardback: 978-0-470-74722-3
April 2010 • 484 pages

E-book: 978-0-470-66067-6

"Tyano, Keren, Herrman and Cox have edited a thoughtfully prepared guide on normal and abnormal parenting. They have, with enormous skill and wisdom, helped to unite the important aspects of pregnancy, infant and childhood development and parenting for adult and child and adolescent psychiatrists. World-class internationally recognized clinicians and researchers help make this book useful throughout the world. This is a masterful, culturally sensitive and important book which provides a long overdue and much needed guide on relationships among children, parents and families."

MICHELLE RIBA
Professor and Associate Chair for Integrated Medical and Psychiatric Services

EDITED BY Nancy Eisenberg

CHILD
DEVELOPMENT
PERSPECTIVES

Edited by
NANCY EISENBERG

Published on behalf of the Society for Research in Child Development

Child Development Perspectives' mission is to provide accessible, synthetic reports that summarize emerging trends or conclusions within various domains of developmental research, and to encourage multidisciplinary and international dialogue on a variety of topics in the developmental sciences.

MONOGRAPHS OF THE
SOCIETY FOR RESEARCH
IN CHILD DEVELOPMENT

Edited by
W. ANDREW COLLINS

Published on behalf of the Society for Research in Child Development

Since 1935 this series has presented in-depth research studies and significant findings in child development and its related disciplines. Each issue consists of a single study or a group of papers on a single theme, accompanied usually by commentary and discussion. Like all Society for Research in Child Development (SRCD) publications, the ***Monographs*** enable development specialists from many disciplines to share their data, techniques, research methods, and conclusions.

A subscription to the ***Monographs*** series also includes a full subscription (6 issues) to ***Child Development,*** the flagship journal of the SRCD, and ***Child Development Perspectives,*** the most recent publication from SRCD.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and ... are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www. srcd.org/web posting. html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org /CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all coauthors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (6th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. If color artwork is submitted, and the authors believe color art is necessary to the presentation of their work, the submissions letter should indicate that one or more authors or their institutions are prepared to pay the substantial costs associated with color art reproduction. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Editor, *Child Development*, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Note to NIH Grantees

Pursuant to NIH mandate, Society through Wiley-Blackwell will post the accepted version of Contributions authored by NIH grantholders to PubMed Central upon acceptance. This accepted version will be made publicly available 12 months after publication. For further information, see www.wiley.com/go/nihmandate.

DEPRIVATION-SPECIFIC PSYCHOLOGICAL PATTERNS: EFFECTS OF INSTITUTIONAL DEPRIVATION
- *Michael Rutter, Edmund J. Sonuga-Barke, Celia Beckett, Jennifer Castle, Jana Kreppner, Robert Kumsta, Wolff Schlotz, Suzanne Stevens, and Christopher A. Bell* (Serial No. 295, 2010).

A DYNAMIC CASCADE MODEL OF THE DEVELOPMENT OF SUBSTANCE-USE ONSET
- *Kenneth A. Dodge, Patrick S. Malone, Jennifer E. Lansford, Shari Miller, Gregory S. Pettit, and John E. Bates* (Serial No. 294, 2009).

FLEXIBILITY IN EARLY VERB USE: EVIDENCE FROM A MULTIPLE-*N* DIARY STUDY
- *Letitia R. Naigles, Erika Hoff, and Donna Vear* (Serial No. 293, 2009).

MARITAL CONFLICT AND CHILDREN'S EXTERNALIZING BEHAVIOR: INTERACTIONS BETWEEN PARASYMPATHETIC AND SYMPATHETIC NERVOUS SYSTEM ACTIVITY
- *Mona El-Sheikh et al.* (Serial No. 292, 2009).

THE EFFECTS OF EARLY SOCIAL-EMOTIONAL AND RELATIONSHIP EXPERIENCE ON THE DEVELOPMENT OF YOUNG ORPHANAGE CHILDREN
- *The St. Petersburg–USA Orphanage Research Team* (Serial No. 291, 2008).

UNDERSTANDING MOTHER-ADOLESCENT CONFLICT DISCUSSIONS: CONCURRENT AND ACROSS-TIME PREDICTION FROM YOUTHS' DISPOSITIONS AND PARENTING
- *Nancy Eisenberg et al.* (Serial No. 290, 2008).

DEVELOPING OBJECT CONCEPTS IN INFANCY: AN ASSOCIATIVE LEARNING PERSPECTIVE
- *David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

THE GENETIC AND ENVIRONMENTAL ORIGINS OF LEARNING ABILITIES AND DISABILITIES IN THE EARLY SCHOOL YEARS
- *Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

THE PRESERVATION OF TWO INFANT TEMPERAMENTS INTO ADOLESCENCE
- *Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

CHILDREN'S QUESTIONS: A MECHANISM FOR COGNITIVE DEVELOPMENT
- *Michelle M. Chouinard* (Serial No. 286, 2007).

BEST PRACTICES IN QUANTITATIVE METHODS FOR DEVELOPMENTALISTS
- *Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

FOUNDATIONS OF SELF-AWARENESS: AN EXPLORATION THROUGH AUTISM
- *R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

OUR CHILDREN TOO: A HISTORY OF THE BLACK CAUCUS
OF THE SOCIETY FOR RESEARCH IN CHILD DEVELOPMENT, 1973–1997
- *Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

PARENTAL SUPPORT, PSYCHOLOGICAL CONTROL, AND BEHAVIORAL CONTROL:
ASSESSING RELEVANCE ACROSS TIME, CULTURE, AND METHOD
- *Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

BEING HURT AND HURTING OTHERS: CHILDREN'S NARRATIVE ACCOUNTS
AND MORAL JUDGMENTS OF THEIR OWN INTERPERSONAL CONFLICTS
- *Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

CHILDHOOD SEXUAL ASSAULT VICTIMS: LONG-TERM OUTCOMES AFTER TESTIFYING IN CRIMINAL COURT
- *Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

THE EMERGENCE OF SOCIAL COGNITION IN THREE YOUNG CHIMPANZEES
- *Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

TRAJECTORIES OF PHYSICAL AGGRESSION FROM TODDLERHOOD TO MIDDLE CHILDHOOD:
PREDICTORS, CORRELATES, AND OUTCOMES
- *NICHD Early Child Care Research Network* (Serial No. 278, 2004).

CONSTRAINTS ON CONCEPTUAL DEVELOPMENT: A CASE STUDY OF THE ACQUISITION OF
FOLKBIOLOGICAL AND FOLKSOCIOLOGICAL KNOWLEDGE IN MADAGASCAR
- *Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

ORIGINS AND EARLY DEVELOPMENT OF HUMAN BODY KNOWLEDGE
- *Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial No. 276, 2004).

MOTHER CHILD CONVERSATIONS ABOUT GENDER: UNDERSTANDING THE ACQUISITION OF ESSENTIALIST BELIEFS
- *Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial No. 275, 2004).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Institutional subscription prices for 2010 are: Print & Online: US$670 (US), US$938 (Rest of World), €608 (Europe), £479 (UK). Prices are exclusive of tax. Asia-Pacific GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wileyonlinelibrary.com/tax-vat. The price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.wileyonlinelibrary.com/access.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit wileyonlinelibrary.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (Americas); +44 (0) 1865 778315 (Europe, Middle East, and Africa); or +65 6511 8000 (Asia Pacific). Subscription in 2010 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from cs-journals@wiley.com. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. Eye on Gender

From early in life, people categorize others according to the social group they belong to, for example, by gender, race, or age. For preschoolers, these determinations often involve gender, with their judgments influenced by superficial aspects of appearance like hairstyle and dress. **Johnson, Lurye, and Tassinary** (p. 1346) find that 4-year-olds' judgments about whether the shape they viewed was male or female were unrelated to body shape. But by age 5, the youngsters had started to rely on more permanent aspects of appearance such as body shape to categorize. And by age 6, their judgments resembled those of adults. Further analyses of how children looked at the shapes find that when they looked toward the waist and hip region, they used that information to make their decisions. The study, which used eye-tracking technology to determine where the more than 100 children studied were looking, furthers our understanding of how youngsters view others.

Bilingual Flexibility

Bilingual children speak two languages and can swiftly move from the use of one language to another. Research has shown that these children develop improved abilities that give them flexibility in learning and using both languages. **Adi-Japha, Berberich-Artzi, and Libnawi** (p. 1356), in a study of 4-year-old English-Hebrew children and 5-year-old Arabic-Hebrew children, find that these advantages in cognitive flexibility even extend to areas beyond language, such as imaginative drawings, with bilingual children showing a form of expressive drawing earlier than monolingual children. The study sheds light on the relations between processes involved in language learning and other symbolic domains.

Spatial Ability

We use spatial ability in our daily lives when we navigate, recall where something is located, and recognize things, and in jobs like engineering, architecture, and surgery. Past research has found that males have better spatial ability than females, with the gender gap starting in infancy and growing with age. In a study of more than 100 first graders in Israel, **Tzuriel and Egozi** (p. 1417) asked: Can training reduce these gender differences? They find that after a relatively long-term training program (the study comprised eight weekly sessions) focused on expanding working memory, perceiving spatial information globally rather than analytically, and thinking about spatial stimuli from different points of view, initial gender differences disappeared. And later, girls who had taken part in the training did better than boys who hadn't. Given the value of good spatial skills in math and science, this study can inform curriculum and intervention programs aimed at overcoming gender differences that many believe are biologically determined.

Researchers typically look at how babies solve problems by examining how they use manual tools and considering spatial relations between the baby, the tool, and the goal at hand. **Berger, Adolph, and Kavookjian** (p. 1367) took a different approach, focusing on the whole bodies of the 16-month-olds studied, not just their hands. They find that youngsters were also able to solve tasks that involved navigating bridges and handrails, suggesting that they could plan solutions that required them to use their whole bodies and to coordinate multiple motor actions in the face of ongoing challenges. The study extends our understanding of early cognitive abilities in young children.

Linguistics: Putting Words in Context

When babies first learn words, do they notice subtle sound differences? Can they distinguish words like *bad* and *dad* when learning their meanings? In the past, evidence suggested that 14-month-olds don't bring their detailed attention to language sounds to bear in learning words. But **Fennell and Waxman** (p. 1376) changed the way the words were presented, making clear that the words were nouns and presenting them in a naming context. They find

that bringing in the notion of reference—a basic feature of human language—changes our understanding of how infants learn words. The findings tell us that infants clearly use sounds that are relevant to the language they're learning (such as the consonants *b* and *d* in English) and that they refine those pertinent sounds over the first year of life to help them learn words. The study can inform language-teaching strategies.

Teens: Racial Identity and Cultural Diversity

In a longitudinal study, **Yip, Seaton, and Sellers** (p. 1431) asked more than 200 Black teens in predominantly White middle and high schools in the Midwestern United States to complete surveys about their friendships and racial identity. They find that Black youths' racial identity—that is, the significance of race in their everyday lives—was more likely to change over the 3 years of the study if they had close Black friends. Racial identity remained stable for Black youths who didn't have a lot of contact with other Black youths. The research suggests that school makeup interacts with friendships to affect adolescents' racial identity, and that having friends of the same race is important for the development of racial identity. Since racial identity has been shown to be a protective factor for mental health, this study has implications for educators.

In the Netherlands, prejudice toward Muslims is said to be relatively high, with half of the participants in a recent nationwide survey saying Muslims threaten the Dutch way of life. In a study with global significance, **Gieling, Thijs, and Verkuyten** (p. 1384) looked at more than 1,000 ethnically Dutch non-Muslim teens to gauge their tolerance toward such current issues as Muslims wearing headscarves and founding separate Islamic schools. They also measured the extent to which the teens believed that cultural diversity is good for society and should be accommodated equitably. The teens expressed moderate to low levels of tolerance, with levels declining with age. While some think that as people get older, their reasoning grows more principled and they become more tolerant, this study finds just the opposite. This could be because older children are increasingly concerned about how Dutch society functions and tend to see Muslim practices as threatening. By shedding light on the different ways adolescents reason about these issues, the study has implications for intervention and education programs.

Insights Into Autism

People with autism are thought to have a specific profile of cognitive strengths and weaknesses, but few studies have tracked children's cognitive skills over time. In a longitudinal study of about 70 children, **Pellicano** (p. 1400) finds that compared with children who don't have autism, children with autism have difficulties appreciating the mental lives of others, problems regulating and controlling their behavior, as well as an enhanced ability to perceive details at age 5–6 and again 3 years later. Yet a closer look at individual children's patterns of performance reveals that not all children with autism display the same profile of cognitive strengths and weaknesses, indicating that profiles of cognitive skills vary from one child to the next. The study also finds that some of the cognitive skills of the children with autism improve over time. The findings help inform our understanding of autism.

When someone near you yawns, it's hard to keep yourself from yawning. Research backs this concept, noting that about half of typical adults yawn after someone else has done so. But what about children—do they do the same? In their study of 120 typically developing 1- to 6-year-olds, **Helt, Eigsti, Snyder, and Fein** (p. 1620) find that although infants begin to yawn spontaneously even before they leave the womb, most children don't appear to be susceptible to contagious yawning until they're about 4. The team also carried out the same study on about thirty 6- to 15-year-olds with autism spectrum disorder (ASD), comparing them to two other groups of children with the same mental and chronological ages. They find that children with ASD are less likely to yawn contagiously than typically developing children, and those children with diagnoses that imply more severe autistic symptoms are much less likely to yawn contagiously than those with milder diagnoses. Given that contagious yawning may signal empathy, this study suggests that empathy (and the mimicry that may underlie it) develops slowly over the first few years of life—and that children with ASD may miss subtle cues that tie them emotionally to others.

Parent–Child Interactions: Talking and Remembering

Past research has shown that the ways mothers talk to their children influence children's understanding of themselves and others. Specifically, mothers who focus on discussing desires, feelings, and thoughts contribute to the way children understand how psychological states like emotions, beliefs, and desires influence behaviors. **Doan and Wang** (p. 1490) asked: Can styles of conversation influence children's understanding of how different situations may elicit different types of emotions? Are there cultural differences, and can they explain differences in children's understanding of emotions? The researchers studied more than 130 middle-class European American and immigrant Chinese moms and their 3-year-olds. Findings: European American mothers were more likely to talk about desires, thoughts, and emotions and to ask their children to talk about their psychological states (such as their feelings, beliefs, and thoughts). Immigrant Chinese mothers, on the other hand, were more likely to talk about behaviors. European American children rated higher than their immigrant Chinese counterparts on tests that measured how well they understood the causes of certain emotions. The findings add to our understanding of the cultural and universal processes underlying emotional development.

How do teens and parents remember specific parts of a disagreement after it's over, is their memory accurate, and does it mesh with what really happened? Over time, as memories fade, how do they fill in the gaps? **Dykas, Woodhouse, Ehrlich, and Cassidy** (p. 1445) looked at almost 200 teens in 11th grade and their parents to determine whether the answers to these questions have anything to do with the kinds of attachment relationships the teens had with their parents. They find that secure teens (those with positive models of attachment) remembered interactions more favorably over time, while insecure teens (those with negative models) showed less favorable memory. A similar pattern held for moms, but not for dads, in relation to their teens' adjustment status. The findings suggest that memories are remembered over time based on how adolescents mentally represent previous experiences with their parents.

Child Care: Quality Matters

More than 12 million U.S. preschoolers are in child care. The findings of a longitudinal study by **Votruba-Drzal, Coley, Maldonado-Carreño, Li-Grining, and Chase-Lansdale** (p. 1460) suggest that child care may have a greater effect on some children than others. The researchers looked at about 350 children from low-income ethnic-minority families when they were preschoolers and again in middle childhood. Based on their child care settings, the study finds that children who attended more responsive, stimulating, and well-structured settings during preschool had fewer externalizing behavior problems (such as being aggressive and breaking rules) in middle childhood. High-quality child care was particularly important for boys and African American children. In highlighting the importance of high-quality child care for low-income children, the study strengthens calls for policy and programmatic efforts to increase low-income families' access to such care.

In many early childhood education programs, children are free to choose from a wide variety of educational materials to play with—this is called free-choice play. **Chien et al.** (p. 1534) studied more than 2,700 kindergarteners (almost 50% of whom were poor) in 11 U.S. states. They find that children who spend much of their classroom days engaged in free-choice play make smaller gains in language and math, compared with children who get either direct instruction from teachers or so-called scaffolding interactions (in which teachers modify their instruction to fit children's changing needs). Children who are given time to work on their own and are guided benefit the most, particularly poor children. The study has implications for policy and practice, suggesting that more quality instructional time spent with teachers, and less free play time without teacher guidance, prepares children better for starting school.

Superheroes, Deities, and More

Most people have ideas about nonhuman or superhuman beings that have extraordinary mental capacities, such as people who seem to have vast stores of knowledge, fictional super-heroes, or all-knowing deities. **Lane, Wellman, and Evans** (p. 1475) sought to determine how and when such concepts develop. They asked 3- to 5-year-olds questions to assess their understanding of extraordinary mental capacities in a variety of beings—including ordinary people and those with extraordinary capacities. They find that 4-year-olds first gain an understanding of human mental abilities (with all their attendant constraints) before they begin to appreciate the extraordinary mental abilities of nonhuman or super-human beings. In other words, children can't appreciate extraordinary mental abilities before they understand the limitations of ordinary minds. The research helps us further understand children's concepts of others, both ordinary and extraordinary.

Child Maltreatment

When they reach school, children in foster care run the risk of such problems as getting failing grades, behaving badly, and dropping out. However, not much is known about how and when these problems develop. **Pears, Fisher, Bruce, Kim, and Yoerger** (p. 1550) studied about 140 children aged 3–6 years—85 of whom were placed in foster care because of maltreatment; the rest lived with their biological parents and had no record of maltreatment. They find that for the foster kids, the problems developed early: By kindergarten and first grade, the foster children were markedly behind their peers in academics and behavior. But the study also finds that foster children with better self-control had better scores in both academics and on behavior. And children whose caregivers were more involved in school also had better scores on behavior. The findings can inform intervention programs to help maltreated foster children before they begin school.

Cicchetti, Rogosch, Howe, and Toth (p. 1504) looked at how children who have been maltreated remember. In a study of more than 300 low-income elementary schoolers, they sought to determine whether maltreated children had different levels of the stress hormone cortisol, and whether atypical levels of cortisol affected the children's basic memory abilities. They find that maltreated children were more likely to have low levels of cortisol in the morning (which can indicate overwhelming stress) but that the experience of child maltreatment per se didn't adversely affect their basic ability to remember. However, among children who'd been neglected or emotionally maltreated, those with low cortisol levels had more memory problems and weren't as accurate identifying words they had seen before. The findings suggest that maltreatment doesn't affect all children in the same way, and that maltreated children in general don't have significant problems with memory. By shedding light on these issues, the study has implications for both intervention programs and forensic investigations.

Boosting Numerical Abilities

Fuchs, Geary, Compton, Fuchs, Hamlett, and Bryant (p. 1520) assessed how basic numerical cognition and several general aspects of cognition, including working memory and reasoning, affect first graders' skills at solving arithmetic and word problems. Results suggest that children's arithmetic and word-problem skills depend on different groupings of numerical versus more general cognitive abilities and that providing opportunities to children to strengthen certain abilities can help build a foundation for formal mathematics learning in school. The study, of more than two hundred 5- to 7-year-olds, underscores the value of starting early—with preschoolers—to help children organize and strengthen their knowledge about numerical values.

Identity in Adolescence

A key component of adolescence is developing a sense of identity. But is identity a stable individual disposition, or does it change during the teenage years? **Meeus, van de Schoot, Keijsers, Schwartz, and Branje** (p. 1565), in a longitudinal study of the development of identity in more than 1,300 Dutch youths aged 12–20, find that identity progresses systematically during adolescence. Their study finds that most teens remain in the same identity over time, and most teens who change identity status over 5 years make only one transition, both of which indicate that changes in identity status tend to be decisive. The research suggests that adolescent identity develops at a regular pace and that, contrary to common assumptions, the majority of adolescents don't experience identity conflicts very often. On the other hand, a substantial group (about 13%) struggles with an insecure identity throughout adolescence; they are the youngsters at risk.

Media: New Views of Screen Time

Educational TV like *Sesame Street* can support children's academic and social-emotional development. **Linebarger and Piotrowski** (p. 1582) conducted two studies to identify features of educational programs that help children understand the programs and build vocabulary. They did a content analysis of learning strategies embedded in educational TV. Then they explored how more than 70 low-income African Americans and English language learners aged 7 through 9 did on tests of vocabulary and comprehension that were related to what they saw on the programs. Two types of shows were considered: narrative programs (those that tell stories to present information) and expository programs (those that present information in a variety of ways). The study concludes: Children learn vocabulary and understand program content better when they watch narrative programs than when they watch expository programs. The findings can help those creating educational TV programs designed to support at-risk youngsters' literacy skills.

Another study addresses a different type of screen time. Between 1997 and 2003, the amount of playtime children spent logged onto the computer and playing video games rose from 21% to 33%. Amid concerns about the effect of unlimited use of new media, **Hofferth** (p. 1598) asked: Does computer and video game use at home contribute to or detract from children's achievement and behavior? Using data from a nationally representative study of children aged 6–12 in 1997 who were followed for 6 years, she finds that the answers to this question differ depending on the children's race and ethnicity, and their gender. More computer time was associated with higher achievement for White and Black girls and Black boys, but not for White boys. Black girls who played more video games were better at solving math problems, but increased game playing meant lower verbal achievement on average for both groups of girls; there were no effects on boys' achievement. And for both groups of boys, more video playing was linked to more aggressive behavior. The study's conclusion: Although bringing minority boys and majority and minority girls up to speed on the computer could boost achievement, it's still important to monitor their video game time.

Sex Categorization Among Preschool Children: Increasing Utilization of Sexually Dimorphic Cues

Kerri L. Johnson
University of California

Leah E. Lurye
New York University

Louis G. Tassinary
Texas A&M University

Two studies examined how children between ages 4 and 6 use body shape (i.e., the waist-to-hip-ratio [WHR]) for sex categorization. In Study 1 ($N = 73$), 5- and 6-year-olds, but not 4-year-olds, selected bodies with increasingly discrepant WHRs to be "most like a man" and "most like a woman." Similarly, sex category judgments made by 5- and 6-year-olds, but not 4-year-olds, varied with WHR. In Study 2 ($N = 41$), eye movements indicated the functional use of waist and hips in sex categorization. Visual scanning behavior predicted the degree of association between WHR and judgment. Collectively, these results suggest that the ability to exploit sexual dimorphism to compel categorization develops between the ages of 4 and 6. Implications for theories of gender development and psychological essentialism are discussed.

Snips and snails, and puppy dogs' tails
That's what little boys are made of!. . .
Sugar and spice and all things nice
That's what little girls are made of!

In the popular rhyme, Mother Goose provided an endearing image about the makeup of little boys and girls. The rhyme's appeal rests, in part, on its vivid analogies for the distinction between boys and girls. Although the content is indisputably false, two aspects of this rhyme are telling. First, the notion that boys and girls, and by extension men and women, embody distinct visual markers to their sex category rings true. Second, the description of social categories that are important, enduring, and meaningful—sex categories—is compelling. Indeed, sex categorization begins early in life, and it relies heavily on visual cues. Moreover, sex categorization exerts considerable influence over subsequent evaluative judgments, leading sociologists to describe sex category as a *master status* (see, e.g., Hughes, 1945). Surprisingly, the basis of children's sex categorizations is not well understood, and most research has focused exclusively on face perception. Here, we examine how preschool children's categorical sex judgments incorporate another cue that reliably distinguishes men from women—body shape.

Men and women differ on a variety of observable attributes. Young children appreciate such cues exhibiting some form of gender knowledge prior to their ability to verbalize it. Before they reach 9 months, infants distinguish faces according to social categories (i.e., sex, Leinbach & Fagot, 1993; Quinn, Yahr, Kuhn, Slater, & Pascalis, 2002; and race, Kelly et al., 2007). By 12 months, children reliably integrate gendered cues originating in different modalities (i.e., faces and voices; Poulin-Dubois, Serbin, Kenyon, & Derbyshire, 1994; Walker-Andrews, Bahrick, Raglioni, & Diaz, 1991). In infancy, sex categories are discernable at a perceptual, if not a conceptual, level.

Young children's ability to label men and women emerges during the 2nd year (Zosuls, et al., 2009). Preschool children rely heavily on superficial cues (i.e., hair and makeup) for sex categorization

---

The authors thank Mike Polito and Casey Levine-Beard for valuable assistance with data collection, Scott Johnson and Diane Ruble for helpful comments on a previous version of this manuscript, Masumi Iida and Jennifer Krull for valuable statistical advice, and the children and their parents for participating in the study. Portions of these data were presented at the 2007 meeting of the Society for Research in Child Development.

(Thompson & Bentler, 1971), even though internal face structure is more reliable (Burton, Bruce, & Dench, 1993). In fact, children are unable to judge the sex of faces devoid of superficial cues until age 7 (Wild et al., 2000). Thus, although young children exploit aspects of appearance that covary with sex to make categorical judgments, they do not utilize sexually dimorphic cues that reliably discriminate men from women. Undoubtedly, children's use of sexual dimorphism for categorization increases throughout development. Yet this process is poorly understood, in part because a preponderance of research focused on face perception.

The importance of the face for person perception is indisputable. In daily life, however, faces are perceived in the context of another sexually dimorphic cue, the body. Furthermore, person perception often occurs from a distance, or visual vantage, that prohibits face processing—forcing perceptions to rely on body cues, many of which are diagnostic of social categories. Both body shape and motion, for example, are sexually dimorphic (Johnson, 2004; Johnson & Tassinary, 2007b; Kerrigan, Todd, & Della Croce, 1998), and adults exploit these differences when making sex categorizations (Lippa, 1983; Pollick, Kay, Heim, & Stringer, 2005). Recent evidence suggests that the body's shape can even be more compelling than its motion for sex judgments (Johnson & Tassinary, 2005).

In children, body knowledge increases with age, first reflecting an understanding of body structure and later revealing a more sophisticated understanding of primary and secondary sex characteristics. Children notice violations of the body's canonical structure quite early (i.e., 15 months; Slaughter & Heron, 2004; Slaughter, Heron, & Sim, 2002; Slaughter, Stone, & Reed, 2004), demonstrating an understanding of the spatial relations among the head, limbs, and torso. By age 3, this knowledge extends to sex-specific structure. Specifically, some children recognize that primary sex characteristics define a target's sex, and can use them for sex categorization even when they are no longer visible and when a target wears cross-sex-typed clothing (Bem, 1989). Under some circumstances, however, superficial cues (e.g., hair) carry more weight in gender labeling. In one study (Thompson & Bentler, 1971), preschool children dressed and labeled dolls as either "Mommy" or "Daddy." These judgments were most heavily influenced by hair length, followed by body anatomy (i.e., secondary sex characteristics), and finally genitals. By age 10, secondary sex characteristics (i.e., body shape) rise in importance and influence more evaluative judgments, such as attractiveness (Connolly, Slaughter, & Mealey, 2004). Thus, young children exhibit increasing knowledge concerning the body's structure, if not an explicit understanding of sexual dimorphism.

In spite of this increase in body knowledge, it is difficult to identify when children notice and use sexually dimorphic cues in social perception. Although some research suggests that young children *can* use primary sex characteristics to inform sex categorization (Bem, 1989), genitals are rarely revealed to others. Instead, observers rely on secondary sex characteristics or adornment cues for sex categorization. To our knowledge, only one study has examined how secondary sex characteristics—the most reliable visual cues under most circumstances—affect sex-typed judgments among children (Thompson & Bentler, 1971), and none has explicitly examined how such cues affect children's sex categorization. Thus, precisely when such cues influence children's judgments remains unclear.

Here we examine whether 4–6-year-old children use body shape, the waist-to-hip ratio (WHR), for sex categorization. This age range reflects a period of rapid changes in children's gender development (Ruble, Martin, & Berenbaum, 2006; Ruble et al., 2007) and increased sensitivity to anatomical sex differences (Thompson & Bentler, 1971). In Study 1, participants completed two tasks—one in which children identified the body that was "most like" a man or woman, and another in which children categorized bodies by sex. In Study 2, we recorded participants' eye movements as they categorized bodies, and we examined visual behavior to discern how children did this.

Study 1

Method

Participants. A total of 73 children (36 boys, 37 girls) between 3.48 and 6.29 years were recruited from an urban community using a commercial database maintained by the department. Four-year-olds ranged from 3.48 to 4.40 years ($M = 4.11$, $SD = 0.21$), 5-year-olds ranged from 4.56 to 5.38 years ($M = 4.97$, $SD = 0.22$), and 6-year-olds ranged from 5.63 to 6.29 years ($M = 6.05$, $SD = 0.17$). Sex distribution was comparable across age group (4-year-olds: 12 boys, 14 girls; 5-year-olds: 10 boys, 9 girls; 6-year-olds: 14 boys, 14 girls). Participants were predominantly Caucasian and came primarily from upper-middle-class backgrounds.

Materials. Stimuli depicted nine computer-generated human bodies that varied in WHR from 0.5 to 0.9 (see Figure 1). Stimuli were rendered in Poser 5™ (Smith Micro Software, Aliso Viejo, CA) using the parameters described in Higa (1999) and Johnson and Tassinary (2007a, 2007b). Bodies were sexually dimorphic in shape but excluded other secondary and tertiary cues to sex (e.g., facial features, body hair, hairstyle, and clothing). These images, and others like them, have been used in research to examine adults' perception of sex categories (Johnson & Tassinary, 2007a, 2007b), attractiveness (Johnson & Tassinary, 2007a, 2007b), and sexual orientation (Johnson, Gill, Reichman, & Tassinary, 2007). These studies found that adult participants perceive the boundary between "female" and "male" bodies to be a WHR of 0.7 (Johnson, 2004; Johnson & Tassinary, 2009). Each image was mounted (separately) on card stock and laminated for durability.

Procedures. Participants were tested individually. We familiarized participants with all stimuli by showing all cards simultaneously, increasing in WHR. We asked participants to identify how the images differed. After the participant indicated that the images differed in body shape (most frequently by pointing to the waist and hips region) participants completed two tasks, in counterbalanced order.

In an identification task, all targets were presented simultaneously. Cards were mounted on a wall, increasing in WHR. Participants stood 2 ft away from the stimuli, and the experimenter drew the participant's attention to the full range by gesturing. Then participants identified which body was "most like a man" and "most like a woman" by placing a sticker on the chosen body. We recorded the corresponding WHR for each selection, which served as the dependent variable in our analysis of these data.

In a categorization task, participants categorized each target's sex by sorting cards into boxes depicting the face of either a man or a woman (left or right placement of boxes was counterbalanced across participants). Participants practiced the procedure by sorting cartoon images (four *Peanuts* characters: Charlie Brown, Linus, Lucy, and Sally) by sex. Then, participants categorized each of the nine targets twice, in two randomized sets.

Results and Discussion

We analyzed data using a generalized equation estimation technique (GEE; Diggle, Liang, & Zeger, 1994; Fitzmaurice, Laird, & Ware, 2004). This permitted us to estimate within-subject parameters for both binary and continuous dependent variables for a fully within-subject factorial design. We use a standard regression vernacular, however, to describe our results. We centered age in years around its mean (i.e., 5.06), and participant sex, and WHR (in integers) at zero. We coded judged sex numerically (0 = *male*, 1 = *female*). We report parameter estimates as unstandardized regression coefficients for all significant effects in Table 1. Task order was initially included as a factor in analyses. It did not affect any dependent variable, and will receive no further mention.

Identification task. We examined whether the bodies identified to be "most like a man" and "most like a woman" varied as a function of age and sex. Thus, the selected WHR was our dependent variable. We regressed WHR onto judgment (i.e., most like man or most like a woman), participant age, participant sex, and all interactions. As predicted, bodies judged to be most like a man had larger WHRs (i.e., .11 units) than bodies identified to be most like a woman, and this varied by age (see Table 1).

We followed up the judgment by age interaction by testing the simple slopes of judgments centered (separately) at each age (see Figure 2 and Table 1). Among 4-year-olds, judgments did not vary significantly with WHR. Among 5- and 6-year-olds, the

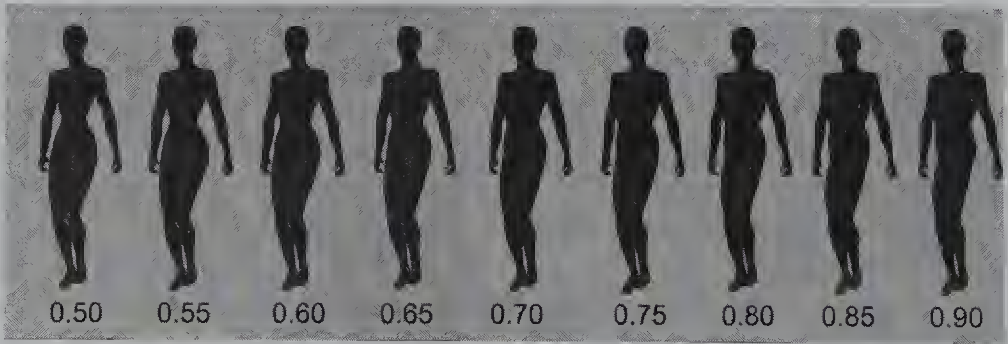

Figure 1. Stimuli depicted nine computer-generated bodies that varied in waist-to-hip ratio from 0.5 to 0.9.

Table 1

Summary of Generalized Equation Estimates (GEE) Predicting Judgments in the Identification and Categorization Tasks of Study 1

Effect	*B*	*SE*	*z*	*p*	Odds ratio
Identification task					
Man/woman	−0.1137	0.021	−5.48	****	N.A.
Interaction (Age × Man/Woman)	−0.0768	0.0219	−3.51	***	N.A.
Simple slope at age 4	−0.0321	0.0289	−1.11	*ns*	N.A.
Simple slope at age 5	−0.1088	0.0206	−5.29	****	N.A.
Simple slope at age 6	−0.1856	0.0311	−5.96	****	N.A.
Categorization task					
WHR	−0.0947	0.0218	−4.33	****	2.35
Interaction (Age × WHR)	−0.0908	0.0252	−3.61	***	—

Sex of participant	0.5077	0.2045	2.48	**	1.66

Note. B values are unstandardized coefficients from GEE. Odds ratio was computed based on the change in judgments of the full range of waist-to-hip ratio (WHR) stimuli (i.e., 0.5–0.9). Nonsignificant main effects and interactions are omitted.
$^{**}p \leq .01$. $^{***}p < .001$. $^{****}p < .0001$.

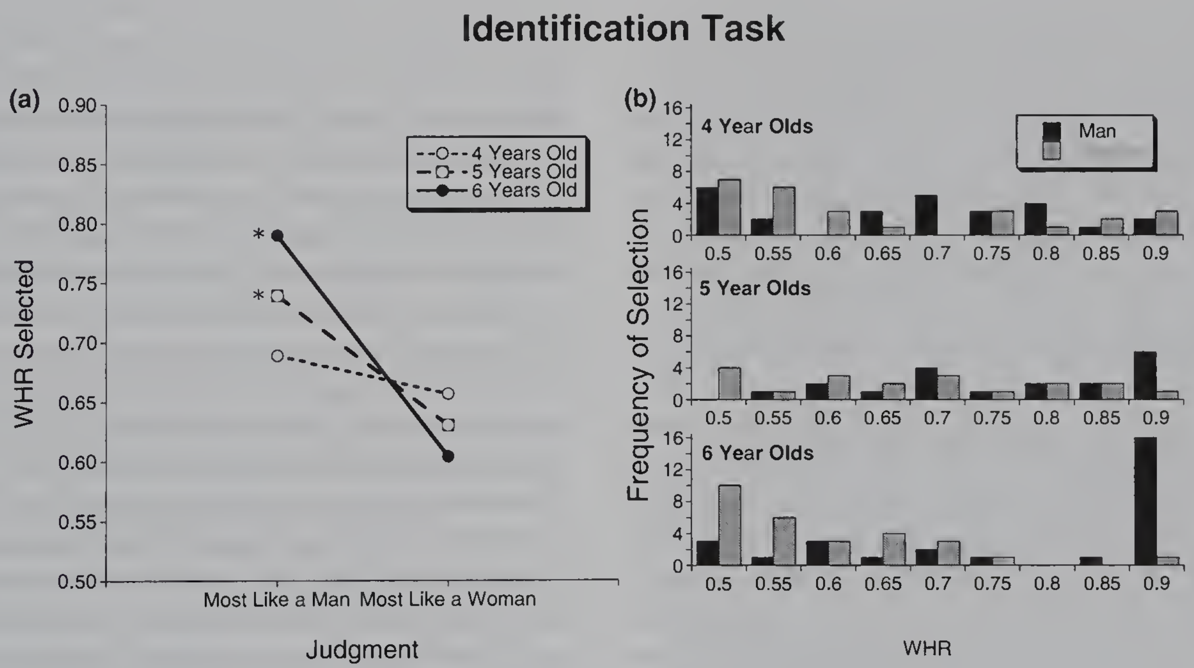

Figure 2. Waist-to-hip ratio (WHR) selected to be "most like a man" and "most like a woman" as a function of age for the identification task. (a) Plots reflect predicted WHR selected for each judgment centered separately around 4, 5, and 6 years of age. (b) Raw frequency that each WHR was selected.

WHR identified to be most like a man was significantly larger than the WHR identified to be most like a woman, simple. Other effects were nonsignificant, all *z*s < 0.91, *ns*.

Categorization task. First, we examined the accuracy of sex categorizations during the practice phase. No errors occurred at any age. Because participants sorted cards twice, we initially included this as a factor in all analyses. No main effects or interactions involving set approached significance (all *B*s < 0.09, all *p*s > .34), and it was therefore dropped from the analyses.

To examine whether sex categorizations varied with age and WHR, we regressed perceived sex onto WHR, participant age, participant sex, and all interactions. As predicted, as the WHR increased, targets were more likely to be categorized as men, and this varied by age (see Table 1).

We followed up the WHR × Age interaction by testing the simple slopes of judgment centered

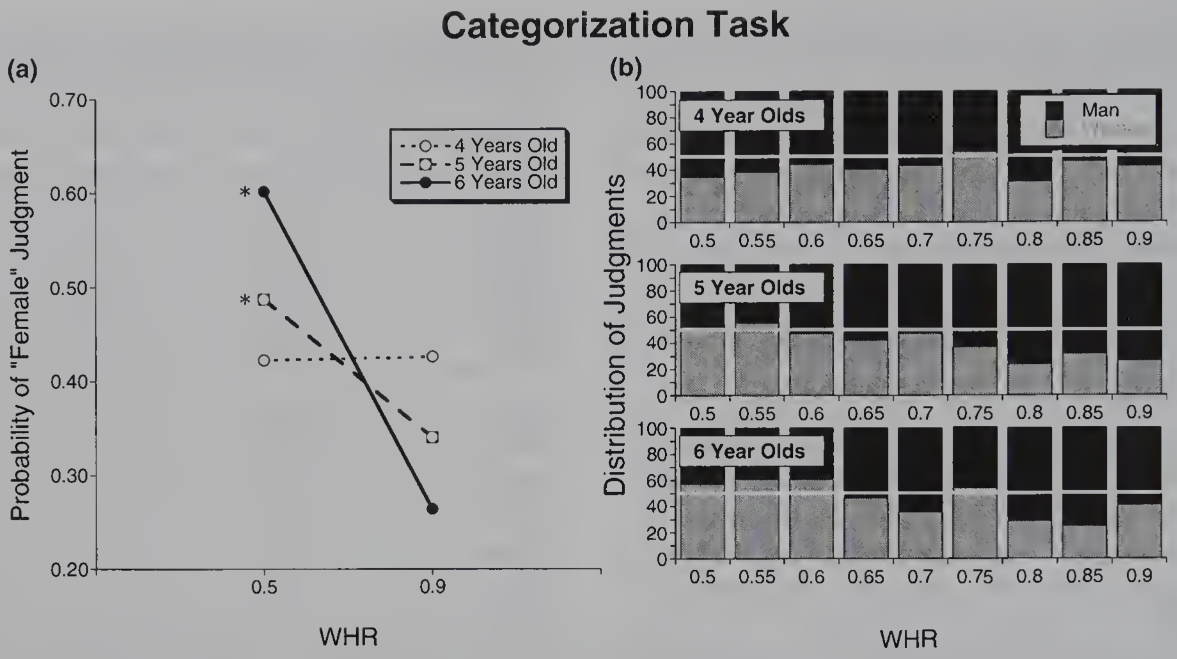

Figure 3. Probability that a target is judged to be female as a function of waist-to-hip ratio (WHR) and age for the categorization task. (a) WHR was treated as a continuous variable in this analysis, and plots reflect predicted probability when the WHR was 0.5 and 0.9, centered separately around 4, 5, and 6 years of age. (b) Raw frequency of male and female categorizations for each WHR.

(separately) at each age (see Figure 3 and Table 1). Among 4-year-olds, judgments did not vary with WHR. Among 5-year-olds, each increase in WHR corresponded to 8.9% more "man" categorizations; among 6-year-olds, each increase in WHR corresponded to 17.98% more "man" categorizations.

Compared with girls, boys were more likely to categorize targets to be men and vice versa (see Table 1). No other effects reached significance, all zs < 1.25, *ns*.

These results suggest that between 4 and 6 years, children increasingly exploit sexual dimorphism for sex categorization. This pattern could occur for many reasons. One possibility is that our tasks were too difficult for 4-year-olds. This seems unlikely. First, 4-year-olds easily and accurately categorized each practice stimulus. Although the demands of each task differed (e.g., relative judgments in the identification task, sorting in the categorization task), the results from both were convergent, suggesting that task difficulty is unlikely to be the explanation. Instead, we propose that 4-year-olds' failure to utilize WHR reflects a lack of knowledge about sexual dimorphism. This could contribute to their failure to utilize the WHR in their judgments in two ways. First, they may not attend to the waist and hips because they do not perceive the region as relevant for sex categorization. Second, they may attend to differences in WHR but fail to relate those differences systematically to sex categorization. These issues concerning younger children's ability to identify and utilize a sexually dimorphic cue cannot be resolved in Study 1. In Study 2, we address these issues by observing children's visual behavior as they categorized our stimuli.

The utilization of the WHR for sex category judgments corresponds to telltale visual behaviors. Using similar stimuli, Johnson and Tassinary (2005) recorded adult participants' eye movements as they visually scanned bodies prior to making social judgments. When participants were required to make sex category judgments, they concentrated visual scanning in the waist and hips, recognizing the region's relevance for the task. In contrast, when the targets' sex was prespecified, thus removing the need to categorize, participants no longer concentrated scanning within the waist and hips. Such measures are also likely to be informative for understanding how children come to use sexual dimorphism for sex categorization. We reasoned that observing children's visual behavior would allow us to determine not only whether children recognize differences across the stimuli but also whether they recognize the region's relevance for their judgments.

Study 2

In Study 2, we tracked children's eye movements as they made sex category judgments. First, we calculated visual scanning within the waist and hips as an index of children's attention toward the relevant cue and examined whether this differed by age. Then we examined whether attention toward this area predicts its use for sex categorization. We predicted that children who look toward the waist and hips would be more likely to show a strong relation between WHR and sex category judgments.

Method

Participants. Participants were forty-one 4- and 6-year-old children (20 boys and 21 girls). The 4-year-olds ranged from 3.73 to 4.25 years (*M* = 3.95, *SD* = 0.12); the 6-year-olds ranged from 5.67 to 6.52 years (*M* = 6.05, *SD* = 0.17). Participants were recruited as described previously. Sex distribution was comparable across age groups (4-year-olds: 10 boys and 10 girls; 6-year-olds: 10 boys and 11 girls).

Procedures. As before, we familiarized participants with the range of stimuli by showing all targets simultaneously, increasing in WHR. After indicating that they perceived differences between the targets, participants completed a computerized categorization task.

Participants were seated approximately 120 cm away from a 43 cm Tobii 1750 (Falls Church, VA) corneal reflection eye-tracker. ClearView software (Tobii Software, Falls Church, VA) presented stimuli and recorded eye movements at 30 Hz, with a spatial resolution within .5° visual angle. Participants were calibrated individually by registering five known fixation points, and confirming their reliability before proceeding.

Stimuli included digitized versions of those used in Study 1 (see Figure 4), and the task was conceptually similar, albeit with virtual rather than real boxes. In this task, the "boxes" appeared as photographs of a man and woman, counterbalanced in order, in the upper corners of the screen. The task was described using an identical script. That is, we instructed participants to determine which box each stimulus belonged in. We familiarized participants with the task—first verbally, then with a practice phase as in Study 1. Then, participants categorized the nine targets twice, in one of two random orders.

Results and Discussion

Preliminary analysis. No participant reported any confusion about the task, and no participant made an error in categorizing the practice stimuli. We confirmed that the basic pattern of judgments replicated using the same analyses described in Study 1. Sex category judgments varied, albeit marginally, as a function of age and WHR, interaction $B = -0.0830$, $SE = 0.0475$, $z = -1.75$, $p = .08$. Among 4-year-olds, judgments did not vary with WHR, simple $B = 0.2600$, $SE = 0.2284$, $z = 1.14$, *ns*. Among 6-year-olds, sex category judgments did vary with WHR, $B = -0.5949$, $SE = 0.2689$, $z = -2.21$, $p = .0269$, odds ratio (OR) = 5.04 (predicted means for WHR of 0.5 = 65% female judgments, and for WHR of .9 = 21% female judgments).

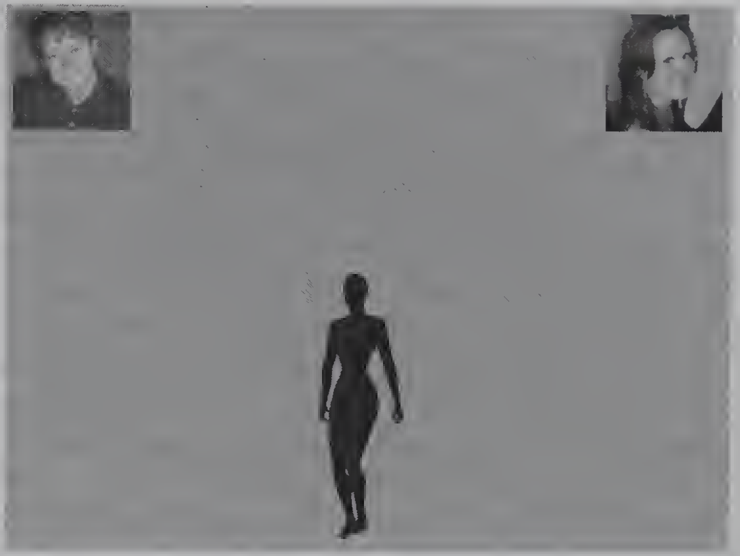

Figure 4. Sample stimulus from Study 2.
Note. The stimulus was centered in the lower portion of the screen; the "male box" and the "female box" appeared in the upper corners (their location was counterbalanced across participants).

Attention to WHR. First, we computed the proportion of body scanning directed toward the waist and hips (hereafter, *Dwell*). Adults tend to increase scanning within the waist/hip when they categorize bodies by sex (Johnson & Tassinary, 2005), but not when the sex of a target is already known. We predicted that a similar difference in scanning would emerge when comparing the scan patterns of children who recognize the relevance of body shape for sex categorization to those who do not. Thus, we suspected that scanning this region might differ with age. Indeed, older children, relative to younger children, looked significantly more to the waist and hips of each body, $B = 0.0368$, $SE = 0.0191$, $z = 1.93$, $p = .05$ (*M*s = 15% and 23%). Importantly, we found no age differences in scanning of the head, chest, or legs (all *B*s < 0.033, all *z*s < 1.5, *ns*). This pattern, combined with the age differences observed in the effect of WHR for categorization, is consistent with our hypothesis that younger children do not fully recognize the relevance of this region as a cue to sex category membership.

Next, we tested this more directly by examining whether visual scanning of the waist and hips predicted children's use of the WHR for their judgments. We used hierarchical linear modeling for this analysis (HLM; Raudenbush, Bryk, & Congdon, 2007). Parameter estimates are shown in Table 2. At Level 1, the analysis modeled the average relation between WHR and judgment. Overall, the two were significantly related. This replicated the overall effect of WHR on judgments that we found in Studies 1 and 2. At Level 2, this analysis examined whether Dwell predicted the strength of the Level 1 relation between WHR and judgments. Not surprisingly, Dwell did not predict judgment directly, but it did moderate the relation between WHR and judgment. As seen in Figure 5, when scanning within the waist and hips was low, the relation between WHR and judgment was negligible. When scanning within the waist and hips was high, in contrast, the relation between WHR and judgment was strong. Importantly, this effect did not differ by participant age when it was included as a Level 2 variable, and scanning within other body regions did not predict the relation between WHR and judgments (all *t*s < 1.81, *ns*).

These results indicate that, as in adults (Johnson & Tassinary, 2005), children's visual scanning of a sexually dimorphic region of the body is functional. Doing so informs sex categorization. Children with elevated visual scanning within the waist and hips showed a strong relation between WHR and judgment; children with no elevated scanning in this area did not. Importantly, this basic effect was not moderated by age. This suggests that younger children's lesser scanning of a sexually dimorphic region of the body occurs because they are less likely to recognize its relevance as a cue for the task at hand—sex categorization—not because they fail to appreciate the differences in the first place. This is important in two ways. First, these findings suggest that the age cohort effects in Study 1 likely reflected a difference in utilization, rather than a wholesale failure of younger children to notice differences between stimuli. Second, this suggests that the use of sexual dimorphism for categorization occurs between ages 4 and 6.

Table 2

Summary of Hierarchical Linear Modeling (HLM) Estimates Predicting Judgments in Study 2

Effect	*B*	*SE*	*t* (*df*)	*p*
Level 1				
WHR	−3.72	1.21	−3.08 (39)	**
Level 2				
Dwell within waist and hips	−1.12	0.79	−1.41 (39)	*ns*
Interaction (Dwell × WHR)	−20.31	8.99	−2.26 (39)	*

Note. *B* values are unstandardized coefficients from hierarchical linear modeling (Raudenbush et al., 2007). WHR = waist-to-hip ratio.
$^{*}p < .05$. $^{**}p < .01$.

General Discussion

These findings begin to fill a gap in the literature that has received minimal attention—how children utilize sexually dimorphic cues in social categorization. In Study 1, we found that between the ages of 4 and 6, children's sex category judgments increasingly covaried with a sexually dimorphic cue, the WHR. Among 5- and 6-year-olds, but not 4-year-olds, targets were more likely to be categorized *male* as the WHR increased. Additionally, across this age range, the WHRs of bodies identified to be most like a man and most like a woman became increasingly divergent, reaching significance by age 5. In Study 2, we demonstrated that increased scanning of this region predicted stronger associations between WHR and judgments. Collectively, these findings highlight a developmental shift between the ages of 4 and 6 in which children become adept at exploiting morphological differences to disambiguate sex category membership.

Because our stimuli were computer generated, we should remain mindful of two things. First, in day-to-day social perception, children's judgments are likely to be informed by multiple visual cues, some of which may take priority over perception of the body. Second, our findings may reveal more about children's judgments of representational media than the actual perception of others. In spite of this, other research suggests that media portrayals of men and women are routinely incorporated into judgments, at times biasing perceptions and preferences (see, e.g., Aubrey & Harrison, 2004; Yu & Shepard, 1998). Therefore, any effects that emerged as a result of the representational nature of our stimuli are likely to be incorporated into perceptions of others as well.

Assuming that our results indicate something general about how children perceive others, the age at which children begin to use sexual dimorphism for sex categorization occurs at a point of rapid transitions in gender development. The increasing awareness that certain visual cues are reliable indicators to a target's sex may demarcate a transition of functional significance—a period during which children shed the notion that one's sex is mutable. Indeed, between 4 and 6 years, young children come to understand the permanence of their own

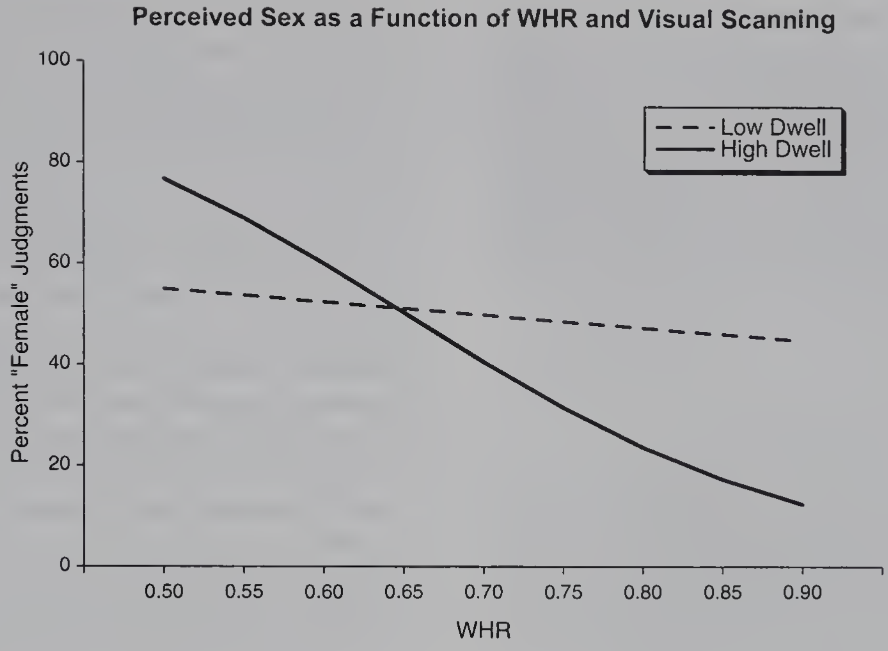

Figure 5. Probability that a target is judged to be female as a function of waist-to-hip ratio (WHR) and visual scanning behavior. *Note.* Plots reflect predicted probability at each WHR, centered separately around low and high Dwell.

sex (gender constancy), a phenomenon researchers have linked to increases in gender stereotype knowledge (Martin, Ruble, & Szkrybalo, 2002; Ruble et al., 2006). An increased reliance on cues that are biologically diagnostic of a target's sex, as opposed to those that are merely correlated with sex, for sex categorization may undergird gender constancy.

Importantly, others have described a functional relation between body knowledge and gender constancy, albeit at a much younger age. Bem (1989) notably found that children who used genitals as the criterion for sex categorization also exhibited some forms of gender constancy by age 3. These findings underscore a minimal age at which children *can* exhibit rudimentary forms of gender constancy, but such effects are likely to be constrained in the real world. In social interactions, for example, genitals are rarely displayed to compel unquestionable categorizations. Instead preschool children are prone to use superficial cues to appearance for categorization (Thompson & Bentler, 1971), and their judgments tend to fluctuate with shifting evidence (e.g., when a boy dons a dress). Malleable sex categorization may be particularly likely when (a) studies use stimuli depicting prepubescent children who are devoid of secondary sex characteristics, and/or (b) children are not equipped to incorporate the dimorphic cues that are visible in stimuli depicting adults. In both cases, children's judgments are more probabilistic than definitively categorical. As children develop an appreciation that sexually dimorphic body cues are visible for fully clothed targets, however, their judgments may shift from reflecting malleable and probabilistic social perceptions to reveal stable categorizations that are less influenced by superficial changes in appearance.

The coincidence of age at which children utilize sexually dimorphic body shape for categorization and at which gender constancy emerges dovetails nicely with research in essentialism. Essentialism refers to the perception that visible cues reveal underlying essential differences between categories (see, e.g., Gelman, 2003). Much of the research in gender essentialism has focused on the perception that stereotyped behaviors emerge from biological rather than social origins, yet the development of such beliefs is informative herein as well. Specifically, we examined young children's ability to infer categories from visual cues (see, e.g., Gelman, Collman, & Maccoby, 1986). From this perspective, children's emerging ability to use sexual dimorphism for sex categorization may reveal a growing awareness of biological differences between men and women and an appreciation that some cues reliably differentiate the two. This reasoning predicts children's increased reliance on sexually dimorphic cues and an emphasis on those cues over superficial aspects of appearance for sex category judgments. Indeed, we found an increased reliance on sexual dimorphism for sex categorization by age 5. The reliance on sexually dimorphic body shape precedes the age at which children's categorization of faces favors sexual dimorphism over superficial cues such as hairstyle (i.e., 5 vs. 7 years). This difference could be because we were seeking the age when children recognize the relevance of sexual dimorphism, whereas prior research in the categorization of faces sought to establish at what age children favor sexually dimorphic cues over superficial appearance cues (Wild et al., 2000). In addition to the research in face perception and gender constancy, our findings provide convergent evidence for the development of essential concepts of men and women in early childhood.

Conclusion

The question of how observers categorize others according to social categories has been an enduring interest of both artists and scientists alike. Although our article opened with an artistic portrayal of the essential characteristics that distinguish boys from girls, our empirical work was decidedly more focused on the perception of a cue that is inherently sexually dimorphic. As such, our findings represent a next step in understanding the development of social categorization—by specifying the age at which children's sex category judgments reflect sensitivity to sexually dimorphic body shape.

Cognitive Flexibility in Drawings of Bilingual Children

Esther Adi-Japha, Jennie Berberich-Artzi, and Afaf Libnawi
Bar-Ilan University

A. Karmiloff-Smith's (1990) task of drawing a nonexistent object is considered to be a measure of cognitive flexibility. The notion of earlier emergence of cognitive flexibility in bilingual children motivated the current researchers to request 4- and 5-year-old English–Hebrew and Arabic–Hebrew bilingual children and their monolingual peers to draw a flower and a house that do not exist ($N = 80$). Bilinguals exhibited a significantly higher rate of interrepresentational flexibility in their drawings (e.g., "a giraffe flower," "a chair-house," found in 28 of 54 drawings), whereas the level of complex intrarepresentational change was similar across groups. Interrepresentational drawings were previously reported only for children older than 7 years. The specific mechanisms by which bilinguals' language experience may lead to interrepresentational flexibility are discussed.

As children develop, they learn to adjust to changing demands and priorities, to consider something from a fresh or different perspective, to switch between perspectives, and to "think outside the box." These behaviors are referred to as "cognitive flexibility" and build on inhibitory control mechanisms and working memory, which are together regarded as core executive skills critical for cognitive development (Diamond, Barnett, Thomas, & Munro, 2007). Current research shows that early bilingualism leads to a developmental advantage in nonlinguistic tasks that necessitate cognitive flexibility (e.g., Bialystok & Senman, 2004; Carlson & Meltzoff, 2008). This advantage exists as early as age 4 (e.g., Bialystok, 1999; Bialystok & Martin, 2004) and is maintained in adulthood (Bialystok, Craik, & Ryan, 2006; Costa, Hernandez, & Sebastian-Galles, 2008).

For over half a century, drawing has been used to study cognitive development (Arnheim, 1956; Freeman, 1995; Golomb, 1974, 1992; Luquet, 1927; Piaget & Inhelder, 1948/1967). Among the variety of drawing tasks that tap into executive skills, Karmiloff-Smith's (1990) task of drawing nonexistent objects is considered to be a measure of cognitive flexibility (Spensley & Taylor, 1999), or representational flexibility (Picard & Vinter, 1999, 2006, 2007), present at that age. Children's skilled graphic production implicates procedural as well as representational aspects. The task allows for few distinct modification categories that involve the relaxation of procedural and representational constraints (Karmiloff-Smith, 1990; Picard & Vinter, 2007). The current study compared the performance of monolingual and bilingual children whose control over specific inhibitory control mechanisms was shown to differ (Carlson & Meltzoff, 2008; Martin-Rhee & Bialystok, 2008).

In the drawing of nonexistent objects task children are asked to draw "an X that does not exist," such as an X they invent, that they have never seen before, a strange X, an X with something funny or odd about it (Karmiloff-Smith, 1990; Spensley & Taylor, 1999). Karmiloff-Smith (1990) showed that in response to a request to draw a man "who does not exist" (and the same for an animal and a house), 4- to 6-year-olds tended to make size, shape, or deletion changes to elements within their drawings, whereas 8- to 10-year-olds exchanged the position of elements, added extra elements from the same representation (e.g., a man with two heads), or included cross-category insertions that involved synthesizing two different representations (e.g., a house with wings).

Different studies that replicated Karmiloff-Smith's (1990) original findings (Berti & Freeman, 1997; Spensley & Taylor, 1999; Zhi, Thomas, & Robinson, 1997) verified a classification of these modifications into two main types of representational flexibilities: An interrepresentational flexibility

observed when a link between components from different categories appears in one drawing (as displayed by cross-category insertions), which emerges at around 8 years, and an intrarepresentational flexibility connected to changes seen in the components of a given graphic representation (as displayed by the other types of modifications), seen already in 4- and 5-year-olds.

Although 4- and 5-year-olds typically did not spontaneously produce interrepresentational changes or complex intrarepresentational changes (i.e., position or orientation change and same-category insertion), they did so when explicitly requested: for example, when asked to draw an animal-man (i.e., a man who is both an animal and a man) and a house-man (Berti & Freeman, 1997); when asked to draw a house with wings or a mushroom with arms (Picard & Vinter, 2007); when given an earlier specific example, for example, a man with wings instead of arms when the task was to ''draw a man with some parts being replaced with parts of an animal'' (Spensley & Taylor, 1999); or when shown a picture they could follow (i.e., a woman with two heads; Zhi et al., 1997). Furthermore, in Spensley and Taylor's (1999) experiment, 4- to 6-year-old children succeeded in drawing examples that were specified verbally, but they were unable to utilize this ability independently. These studies suggest a developmental constraint: Children who are less than 7 years of age cannot respond to the task ''draw an X that does not exist'' with complex representational change without being primed by an explicit example that they can follow carefully, or without being instructed to produce a specific type of insertion.

Further experiments verified that complex intrarepresentational as well as interrepresentational modifications were associated with procedural flexibility (Hollis & Low, 2005; Picard & Vinter, 1999, 2007). However, the notion that interrepresentational flexibility crucially requires the relaxation of a constraint of independence between representations may suggest different pathways to cognitive flexibility for complex intrarepresentational and interrepresentational change in terms of the inhibitory control processes implied.

In this study, drawing of nonexistent objects made by 4-year-old English–Hebrew and 5-year-old Arabic–Hebrew bilingual children were compared with those made by their Hebrew-speaking monolingual peers. Representational innovations made by 4-year-olds are of special interest because at this age children just master their representational skills (Thomas & Silk, 1989). Previous studies of 4-year-old bilingual children verified their advantage in tasks that tap cognitive flexibility (Bialystok, 1999; Bialystok & Martin, 2004). In our pilot studies, we saw that a man, a house, or an animal were too difficult for children aged around 4, whereas a flower was reasonably drawn by most children of that age. At the age of 5 years we saw that although a house was reasonably drawn, an animal was still too difficult to draw, and when these children were requested to draw a nonexistent man, some irrelevant responses (e.g., a dead man) emerged. In Study 1, 4-year-old English–Hebrew bilinguals and their monolingual Hebrew-speaking peers were therefore asked to draw a flower and a flower that does not exist. In Study 2, 5-year-old Arabic–Hebrew bilinguals and their monolingual Hebrew-speaking peers were also asked to draw a house and a house that does not exist. The Arabic–Hebrew bilinguals were tested as a second bilingual group and to control for the possibility that the different direction of writing (right-to-left in both Arabic and Hebrew, as opposed to English) may contribute to the grapho-motor flexibility in the English–Hebrew bilinguals' production. If indeed bilinguals are more successful in drawing nonexistent objects, this will comprise further support for the notion that flexibility in the linguistic domain may facilitate flexibility in other nonlinguistic domains.

Study 1

Method

Participants

Twenty-five monolingual children (12 boys and 13 girls) and 25 bilingual children (13 boys and 12 girls) participated in this study. The participants were 4-year-olds (range = 42–60 months, $M = 49.76$, $SD = 3.79$ months and $M = 51.12$, $SD = 4.75$ months for the monolingual and bilingual children, respectively). The monolingual children attended a private Hebrew kindergarten. The bilingual children attended a private English–Hebrew bilingual kindergarten. The kindergartens were in the same neighborhood, which is located in an upper-middle-class Israeli suburb, and operated for at least 9 hr a day.

For the bilingual group, kindergarten teacher reports ensured that the children participating in the study had acquired their English from home. In this group, either both parents were native English speakers who spoke both English and Hebrew at home and in the community, or one parent spoke English and the other spoke Hebrew.

Procedure

Children were observed individually in a quiet room at their kindergarten. Testing took place in 1–2 sessions (session time did not exceed 20 min). Bilingual children had an additional session for the English vocabulary test. Summer drawing always preceded the nonexistent flower task (see next). The experiment took place in 2 successive years with similar results.

Measures

Peabody Picture Vocabulary Test–III. The Peabody Picture Vocabulary Test–III (PPVT–III; Dunn & Dunn, 1997) is a test of receptive vocabulary. Bilingual children were tested using the English PPVT–IIIA. Following the general procedures of Bialystok (1988), the monolingual and bilingual children were tested on an expert translation of the PPVT–IIIB developed at Bar-Ilan University (see also Bialystok, Shenfield, & Codd, 2000). Different forms of the test were used such that there was no overlap in the specific vocabulary tested. Testing continued until the child made 8 errors out of a block of 12 trials. Raw scores are reported.

The visual reception test. This test was taken from the Illinois Test of Psycholinguistic Abilities (ITPA; Kirk, Mccarthy, & Kirk, 1968) and measures the ability to infer meaning from pictures. During the test, the child is presented with a picture for 3 s. On the following page, the child is requested to identify one of four pictures, which resembles the image on the previous page.

Drawing summer. The children were asked to draw the summer. This drawing was used to test their free drawing skills. Drawing complexity was measured using the Kellogg Scale (see next).

''Draw a flower that does not exist'' test. The children were first asked to draw a flower. After completing their drawing, they were requested to draw ''a flower that does not exist.'' Several phrasings were used to enable the children to understand the task: A flower you invent, you have never seen before, a strange flower, with something funny/odd, something make-believe, pretend. After drawing the nonexistent flower, the children were asked to verbalize why such a flower does not exist. Following the procedure developed by Karmiloff-Smith (1990), two independent judges scored the categories of changes as no change, deletion of elements, insertion of new (same-category) elements, change in element shape or size, whole-shape changes, position or orientation changes, and cross-category insertions. Cohen's κ coefficients for interrater agreement were above .9 ($p < .001$) in all change categories. Disagreements were settled by discussion. As in the original study, the categories were not mutually exclusive.

The drawing was classified as showing change if the nonexistent flower violated ''flowerness.'' Similar flower and nonexistent flower, a bigger and smaller flower, or a flower and a different flower were classified as not showing change, even if the verbal response indicated some difference (e.g., this flower does not exist because ''something shines on it'' or ''because it is green, in make-belief'').

The drawing complexity scale. The Kellogg Scale was used to score the complexity of the drawings of the summer, flower, and nonexistent flower. This scale has seven figural prerepresentational complexity levels (Kellogg, 1970; Golomb, 1992): (1) *scribbling*; (2) placing scribbling marks in *patterns*; (3) scribble constellation that constitutes *emergent diagrams* in the shapes of circles, ovals, triangles, rectangles, or crosses; (4) six outlined figures comprise the stage of *diagrams*—the rectangle, the oval, the triangle, the Greek cross, the diagonal cross, and the odd shape that is closed but irregular; (5) shapes that incorporate two diagrams are termed *combines*; (6) shapes that incorporate three or more diagrams are termed *aggregates*; and (7) complex graphic formulas joined into figures that are devoid of pictorial intention or likeness to an object. Three more levels were added because the tasks used in this study explicitly requested drawings that resemble a known object (representations corresponding to summer or flower) that incorporate a relatively simple scheme (at least at the complexity of a combine, as in item 5). These levels include: (8) a recognizable figure composed of two line objects (e.g., in the flower drawing a center and petals; a stalk and an outline of a flower or circle); (9) a recognizable figure composed of three line objects (e.g., in the flower drawing a stalk, a center, and petals); and (10) a recognizable figure that includes complex graphic formulas. For the summer drawing, the most complex element in the drawing was scored. The two independent judges who scored the drawings for the change categories also scored the drawings for complexity. The scores ranged between 2 and 10. Interjudge agreement was, on average, .96. Cohen's κ coefficients for interrater agreement on a categorical scale were, on average .73 ($p < .001$), and weighted

κ coefficients for an ordinal scale were, on average .92 ($p < .001$). Kellogg Scale scores of the three drawing tasks were significantly correlated, $r(50) > .75$, $p < .001$, and significantly correlated with age $r(50) > .51$, $p < .001$.

Results and Discussion

Monolingual and bilingual children performed similarly on the PPVT–III test, and had similar visual reception and drawing complexity scores (Table 1). Furthermore, the bilingual group had comparable language skills in Hebrew and in English, $t(24) = 1.73$, *ns*. Although similar language skills in monolingual and bilingual young children are not common, similar findings were reported in other studies (e.g., Davidson, Jergovic, Imami, & Theodos, 1997).

As in the original study, we used six change categories (see Method), with a slight difference: Changes in the position of flower elements did not appear. Change categories were not mutually exclusive (Karmiloff-Smith, 1990). Drawings were classified as having 0–4 category changes with most children (45/50) producing 0–2 changes (Picard & Vinter, 2007).

Table 2 presents the number of children in each of the "object that does not exist" categories of change (Karmiloff-Smith, 1990). Monolinguals' most frequent change was deletion (Figure 1), whereas bilinguals' most frequent change was cross-category insertions (Figure 2). Differences between groups in these categories were significant —for deletion, $\chi^2(1) = 6.35$, $p < .05$, and for cross-category insertions, $\chi^2(1) = 11.53$, $p < .001$—although deletion results should be interpreted with some caution given that multiple chi-square tests were performed without making an adjustment in the alpha level. The 13 cross-category insertions made by the bilingual children consisted of modified flowers that included human features (7 children) and those that included animal features (6 children).

As can be seen from the figures, children's verbal response helped explain the drawings' content (Adi-Japha, Levin, & Solomon, 1998). The verbal description matched production in 43 of the 50 children who participated in the study (22 monolinguals and 21 bilinguals). One child did not respond. Overall, the drawing descriptions of 13 bilingual versus 2 monolingual children were of a cross-category type (e.g., Figure 1a) or reflected a cross-category insertion (e.g., Figure 1b), $\chi^2(1) = 11.53$, $p < .001$, whereas the response of 12 monolingual versus 3 bilingual children reflected a deletion, $\chi^2(1) = 7.71$, $p < .01$.

About half of the monolingual children but only one fourth of the bilinguals exhibited deletion as a significant change. This difference was reflected in the drawings' complexity scores. A comparison of the Kellogg Scale scores revealed that among the monolinguals, the regular flower was drawn with a higher level of complexity (Wilcoxon signed rank test, $Z = 2.12$, $p < .04$), whereas no such difference was observed for the bilinguals ($Z = 1.52$, $p > .1$).

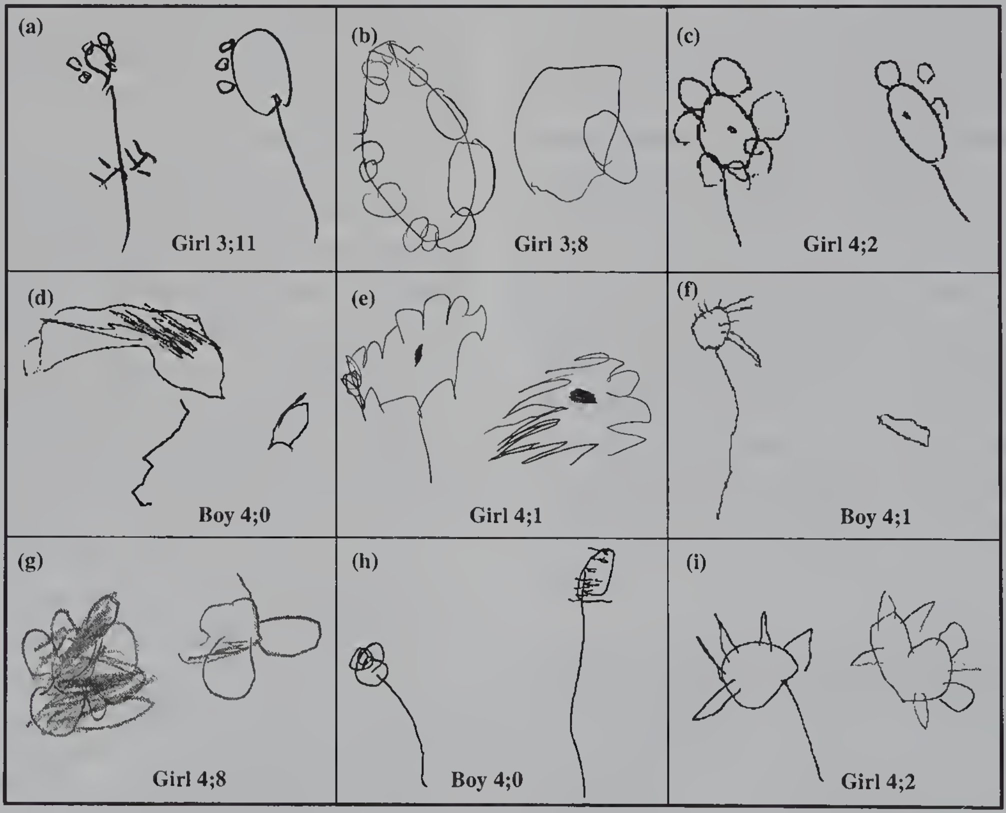

Figure 1. Deletion drawings by monolingual children.
Note. The child's verbal response and (in parentheses) the Kellogg Scale scores for regular and strange flowers are presented for each drawing. (a) "It's missing leaves" (9; 6). (b) "This is not real a flower because it has only one petal" (7; 4.5). (c) Didn't answer (9; 6). (d) "This is not real a flower because it doesn't have a stalk" (4.5; 4). (e) "This is not real a flower because it doesn't have roots" (9; 8). (f) "This is not real a flower; it doesn't have a stalk" (9; 8). (g) "This is not real a flower because it doesn't have the center" (8; 8). (h) "This is a flower in the wind, it doesn't have leaves" (8; 8). (i) "A flower which is a heart." Deletion (of stalk) is a subcategory in this example (9; 9).

The findings of Study 1 indicate that the 4-year-old English–Hebrew bilingual children and their monolingual Hebrew-speaking peers were comparable on a set of background measures. In spite of this similarity, the children produced different types of modifications: Monolingual children exhibited significantly more changes that involved deletion of elements within their drawing; bilingual children inserted significantly more features of other representational categories in their drawing of a flower. The results of Study 1 support the possibility that 4-year-old bilingual children display a

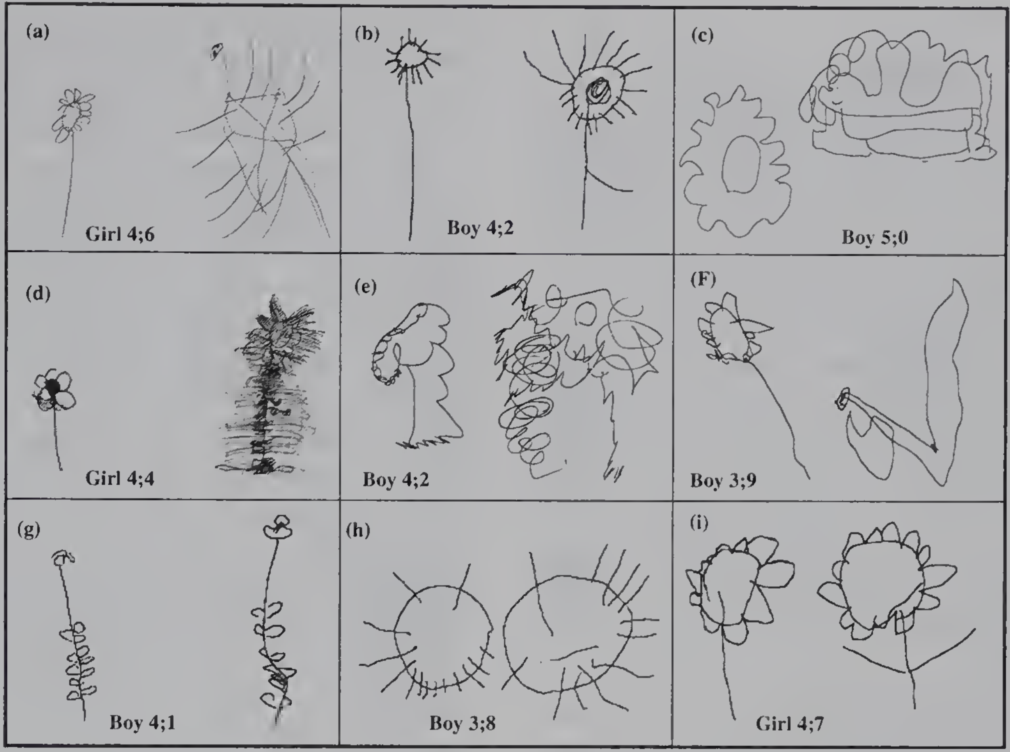

Figure 2. Cross-category insertion drawings of bilingual (English–Hebrew) children.
Note. The child's verbal response and (in parentheses) the Kellogg Scale scores for regular and strange flowers are presented for each drawing. Responses in italics were originally given in English. (a) *This is a giraffe flower* (9; 9.5). (b) *This is a flower with* a tail (9; 9). (c) *This is a camel flower* (8; 8.5). (d) *This is a lion flower with lots of hair. It has a lot of tails and shoes* (9; 10). (e) *This is a silly flower with arms and legs* (6; 4). (f) "This is not a real flower because it has arms and legs" (9; 6). (g) *This flower has teeth; it doesn't want to brush them*" (8.5; 9). (h) "*This is a flower* that knows how to smile" (6; 6). (i) "This is a flower with hands" (9; 9).

different pattern of changes than their monolingual peers, and that this difference is related to the larger portion of cross-category insertions seen in their drawings.

Hebrew and English differ in direction of writing: Hebrew is (read and) written from right to left. This may lead to greater graphic flexibility by English–Hebrew bilinguals. To control for this possibility, in Study 2 Arabic–Hebrew bilingual children were tested as a second bilingual group that share writing characteristics, including direction of writing, with their monolingual Hebrew-speaking peers.

Study 2

Method

Participants

Fifteen monolingual (6 boys and 9 girls) and 15 bilingual children (6 boys and 9 girls) participated in this study. The participants were 5-year-olds (range = 42–74 months, $M = 61.00$, $SD = 9.47$ and $M = 61.87$, $SD = 11.14$ months for the monolingual and bilingual children, respectively). The children participating in the study came from centrally located areas in Israel, came from middle-class families, and had parents who had higher education experiences. The children attended Hebrew-speaking kindergartens for at least 9 hr a day.

The bilingual children came from Muslim families. Bilingual participants attended a Hebrew-speaking kindergarten for not less than 2 years, at least from their 2nd year of life. These children came from an Arab town and attended a kindergarten in one of the nearby kibbutzim. Before their child entered kindergarten, the parents spoke with their children in Arabic. These children can therefore be classified as early sequential bilinguals (Kan & Kohnert, 2008). After their child entered kindergarten, at least one parent (usually the mother) spoke to the child in Hebrew. The parents' Hebrew level was sufficiently high to do so, partly because of their experiences in higher education, where the language of instruction is Hebrew, and experience at their work place.

Procedure

All children were observed individually in a quiet room at their kindergarten. Testing took place in 2–3 sessions (session time did not exceed 20 min). Arabic and Hebrew vocabulary tests were administered in separate sessions.

Measures

The PPVT–IIIA was translated into Arabic by an expert. The drawing summer assessment was not used (as a result of a ceiling effect), and a forward digit span test was added to ensure compatibility of groups.

Forward digit span. This test was used as an assessment of short-term memory. The children were presented with a random string of digits and were required to repeat the string back in the same order. The strings began with two digits and increased by one digit every two trials. One point was awarded for every correctly reproduced sequence, producing the possibility for two points for each string length. Testing ended when the child incorrectly reproduced both sequences at a given string length.

"Draw a flower/house that does not exist" test. The procedure detailed in Study 1 was used. The same phrasing was used to describe a flower and house that do not exist. The flower and house tasks were administered with 1–2 weeks separation, half of the children began with a house, and half with a flower. As a result of the absence of one child, only 14 bilingual children completed the house drawing. Cohen's κ coefficients for interrater agreement were above .92 ($p < .001$) in all change categories.

The drawing complexity scale. The complexity scoring procedure detailed in Study 1 was used except for Levels 8 and 9. Level 8 was applied when the house included either a door or window. Level 9 was applied when both appeared. Scores ranged between 2 and 10. Interjudge agreement was, on average, .94. Cohen's κ coefficients for interrater agreement on a categorical scale were, on average .76 ($p < .001$), and weighted κ coefficients for an ordinal scale were, on average .93 ($p < .001$). Kellogg Scale scores of drawing tasks were significantly correlated, $r(28) = .68$, $p < .001$, and significantly correlated with age $r(29,30) > .52$, $p < .001$.

Results and Discussion

Monolingual and bilingual children performed similarly on the forward digit span test, and had similar visual reception and drawing complexity scores (Table 1). However, monolinguals obtained significantly higher scores than their bilingual peers on the PPVT–III, $t(28)=3.14$, $p < .01$. A paired-sample *t* test indicated that the bilingual group had comparable language skills in Arabic and in Hebrew, $t(14) = 1.49$, *ns*. Other studies have shown that preschool bilingual children who first experience one language, but early on experience the second language, may have similar vocabularies in both languages (Kan & Kohnert, 2008).

Six change categories were used for both the flower and the house drawings, with a slight difference from Study 1: A change in the position or orientation of elements was exhibited only in nonexistent houses. Drawings were classified as having 0–4 category changes with most children (28/30 and 23/30 for the flower and house, respectively) producing 0–2 changes (Picard & Vinter, 2007). Overall, the children responded similarly to the nonexistent flower and house tasks: McNemar tests applied to each of the change categories revealed consistent modifications ($p > .13$); Wilcoxon tests showed that the overall number of change categories ($Z = .98$, *ns*), as well as drawing complexities ($Z = .99$, 1.06, *ns*, for the regular and nonexistent objects, respectively) were similar.

Table 2 presents the number of children in each of the change categories (Karmiloff-Smith, 1990). Compared with Study 1, children's modifications were distributed more evenly across the modification categories. Nevertheless, bilingual children produced significantly more cross-category insertions in the nonexistent flower as well as in the nonexistent house drawing (Figure 3). Eleven bilingual children produced at least one cross-category drawing compared with only four monolingual children, $\chi^2(1) = 6.53$, $p < .02$. In addition to human (5/15 drawings) and animal (3/15 drawings) features added to the flower and house, in Study 2 bilingual children replaced the flower (3/15 drawings) and house (4/15 drawings) with objects (e.g., a flower-door, a ball-house). Except for 2 children (1 monolingual and 1 bilingual) who did not provide a verbal response, children's verbal responses matched drawn modifications, and differences between the two groups in cross-category verbal responses paralleled differences in cross-category drawn modifications.

The findings of Study 2 indicate that the 5-year-old Arabic–Hebrew bilingual children and their monolingual Hebrew-speaking peers were comparable on a set of background measures but differed in their language skills. In spite of this difference, and similar to the findings of Study 1, bilinguals exhibited significantly more cross-category insertions in their drawings of nonexistent objects than their monolinguals peers. In Study 2, the children were requested to draw two nonexistent objects: a flower and a house. The results showed a consistent pattern of production and modifications in the

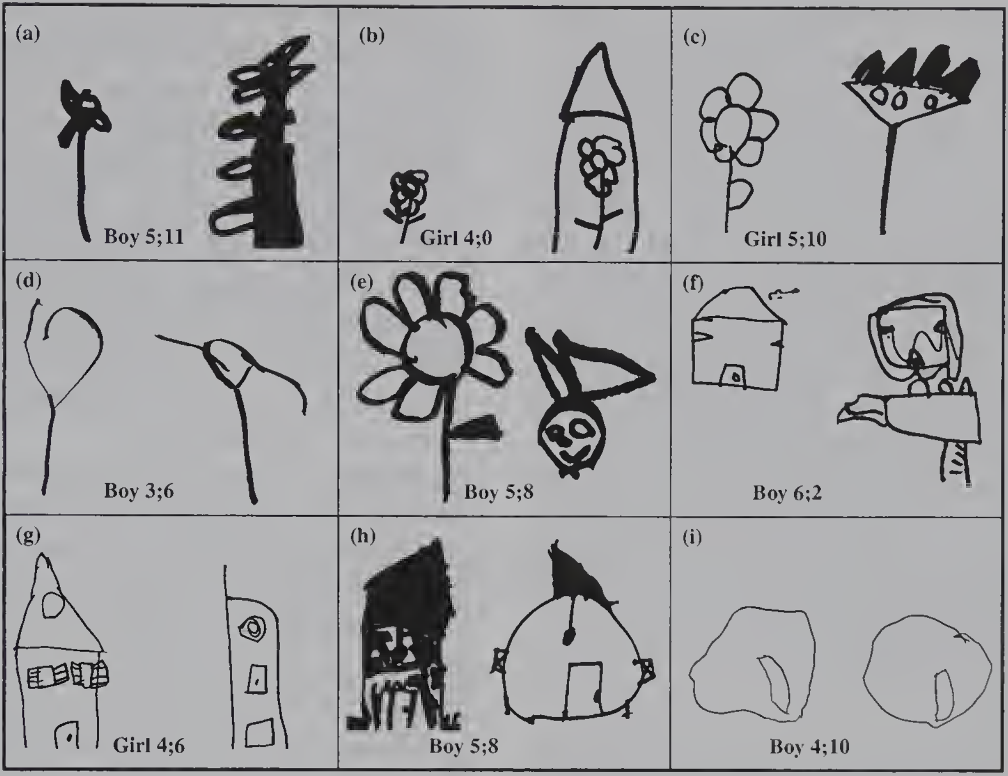

Figure 3. Cross-category insertion drawings of bilingual (Arabic–Hebrew) children.
Note. The child's verbal response and (in parentheses) the Kellogg Scale scores for regular and strange flowers are presented for each drawing. Responses in italics were originally given in Arabic. (a) "This is a tree flower" (9; 9). (b) *This flower is a door* (9; 9). (c) "A butterfly flower" (9; 8.5). (d) "This is a kite flower" (5; 6). (e) *This is a girl flower* (9; 9). (f) "A robot house" (9; 10). (g) "This is a chair house" (9; 8). (h) *This is a ball which is a house* (10; 9). (i) "This is an orange flower" (8; 8).

drawings of these objects. This may be related to the fact that both these objects are frequently produced by 5-year-olds. Furthermore, the rate of deletions of object features was similar across the groups, mainly because of a reduction in the rate of deletions produced by monolingual children. This reduction, albeit nonsignificant (Z = 1.93, in the comparison of two nonexistent flower drawing tasks made by monolinguals in Studies 1 and 2), may be related to the older age of the participants in Study 2.

General Discussion

Studies of representational flexibility consistently replicate the finding of a developmental constraint: Children less than 7 years do not respond to the task "draw an X that does not exist" with a complex intrarepresentational or interrepresentational innovation. The findings of this study indicate that 4- and 5-year-old bilingual children can produce a variety of interrepresentational modifications (i.e., cross-category insertions) in response to the experimenter's request to draw a flower (a house) that does not exist. These results underscore the difference between interrepresentational and intrarepresentational changes and suggest that bilinguals' language experiences may advance the former, but not on the latter type of representational flexibility.

Two samples of bilingual children participated in the study: 4-year-old English–Hebrew simultaneous bilingual children and 5-year-old Arabic–Hebrew early sequential bilingual children. As in previous studies, the atypical performance of the bilingual children was apparent already at age 4. Differences between groups were qualitative as well as quantitative and were probably not the result of the specific language groups compared, or specific object used in the task. Although the finding that 4- to 6-year-olds do not spontaneously produce cross-category insertions was replicated in several studies, and the advantage of 4-year-old as well as the 5-year-old bilinguals in introducing cross-category insertions was robust, future studies are needed to replicate the current results in a more heterogeneous sample of language backgrounds.

Why would bilinguals produce interrepresentational innovations earlier than their monolingual peers? Previous studies have shown that bilinguals exhibit better comprehension of figures or objects that comprise interrepresentational cues (Bialystok & Martin, 2004; Bialystok & Senman, 2004; Bialystok & Shapero, 2005). For example, bilinguals have demonstrated superior performance on an ambiguous figure task when required to identify the alternative image in a reversible figure (e.g., rat-man). It is possible that these children also have a superior ability to create (or at least imagine) figures that convey two representational meanings and that may enhance the frequency of drawings depicting interrepresentational flexibility. The results of several studies support the notion that bilinguals simultaneously keep their two language systems active and switch between them (e.g., Hernandez, Dapretto, Mazziotta, & Bookheimer, 2001; van Heuven, Schriefers, Dijkstra, & Hagoort, 2008). Bilingual children spontaneously switch from one language to another in case of a lexical gap, creating mixed-language sentences (e.g., Lindholm & Padilla, 1978; Nicoladis & Secco, 2000). An early experience in mixing representational systems may as well enhance the frequency of interrepresentational modifications.

Several studies suggest that advantages in executive functions in bilinguals are specific rather than general (Carlson & Meltzoff, 2008; Martin-Rhee & Bialystok, 2008). In line with these findings, the results of Studies 1 and 2 suggest that bilinguals did not demonstrate an overall flexibility advantage. Such an advantage would have been manifested if a higher rate of position and orientation changes, same-category insertions, and cross-category insertions would have been found in their drawings. Rather, bilinguals' performance was different from that of their monolingual peers in just one (of three) categories: Bilingual children produced more cross-category insertions.

Although drawing order was not systematically recorded, it was noticed that most bilingual children either added the cross-category item/s at the end of the drawing procedure (Figures 2b,d,g–i and 3d,f) or from first stroke made a new, blended, figure (Figure 2a,c,f and most drawings in Figure 3). For that to occur, children need to develop inhibitory control mechanisms allowing them to manage two conflicting demands (e.g., that the depicted figure would be recognizable *both* as a flower and as a giraffe). The production of position and orientation changes and same-category insertions typically involves graphic modifications that are executed in the middle of the drawing sequence (the child begins to draw, executes the graphic modification, and then goes on to finish the drawing as usual; Hollis & Low, 2005; Zhi et al., 1997). Graphic interruptions in the middle of the drawing procedure necessitate impulse control. Recent studies suggest that bilinguals have an advantage in the former inhibitory control mechanism (managing conflicting demands) but not in the latter (impulse control; Carlson & Meltzoff, 2008; Martin-Rhee & Bialystok, 2008). This may explain why bilinguals excelled only in the interrepresentational category of change. Drawing is a complex skill involving biomechanical, fine-motor, perceptual, cognitive, and other developmental competencies that do not vary by language (Braswell & Rosengren, 2008; Freeman & Adi-Japha, 2008; Morra, 2005; van Sommers, 1984). It is possible that these factors minimize the differences in representational flexibility that are expected in bilinguals.

Previous research has shown that bilingual children excel in cognitive flexibility tasks requiring a response to bivalent *perceptual* cues (e.g., Bialystok & Martin, 2004; Carlson & Meltzoff, 2008). This study extends the scope of these results to an imaginative cognitive flexibility task from a symbolic *production* domain (i.e., drawing), enabling an unlimited set of responses. Our findings suggest that the cognitive advantage of bilinguals is limited rather than general: Bilinguals produced more interrepresentational (but not intrarepresentational) modifications to their drawings of nonexistent object. The findings of this study provide further support for the notion that flexibility in the linguistic domain may facilitate flexibility in other nonlinguistic domains demonstrating the effects of experience (and in particular bilingualism) on children's development (Emmorey, Luk, Pyers, & Bialystok, 2008; Karmiloff-Smith, 2009). Representational as well as procedural aspects of graphomotor skills (e.g., drawing and writing, and in general any motor skill) improve with experience (e.g., Adi-Japha & Freeman, 2000, 2001; Adi-Japha, Karni, Parnes, Loewenschuss, & Vakil, 2008; Adi-Japha et al., 1998; Adi-Japha et al., 2007). Symbolic representation consists of other domains such as play or sculpture. Experience in symbolic domains is considered essential for cognitive development and the nurturing of executive skills (Diamond et al., 2007). Symbolic domains may provide bilingual children with a natural environment for presenting and enhancing their relative advantage.

Bridging the Gap: Solving Spatial Means–Ends Relations in a Locomotor Task

Sarah E. Berger

Karen E. Adolph and
Alisan E. Kavookjian
New York University

Using a means–means–ends problem-solving task, this study examined whether 16-month-old walking infants (N = 28) took into account the width of a bridge as a means for crossing a precipice and the location of a handrail as a means for augmenting balance on a narrow bridge. Infants were encouraged to cross from one platform to another over narrow and wide bridges located at various distances from a wooden handrail. Infants attempted to walk over the wide bridge more often than the narrow one and when the handrail was within reach. Infants demonstrated parallel problem solving by modifying exploratory behaviors and bridge-crossing strategies that simultaneously accounted for the spatial and functional relations between body and bridge, body and handrail, and bridge and handrail.

Means–ends problem solving is an important cognitive and motor achievement. It requires coordinating environmental supports with relevant body parts to extend the body's capabilities and monitoring multiple spatial and functional relations between actor, goal, and means. Pulling a cane to retrieve an out-of-reach toy, for example, requires recognition that the toy is beyond arm's reach and that a cane could extend the body's limits, implementation of an appropriate grasp of the handle, and understanding that the toy must be positioned inside the crook of the cane (e.g., Chen & Siegler, 2000; McCarty, Clifton, & Collard, 2001; van Leeuwen, Smitsman, & van Leeuwen, 1994). Changing frames of reference present a challenging "localization problem" (Lockman, 2000). Even preschoolers err in simple object-retrieval and spoon tasks after a change in the spatial relations between hook and toy or between hand and spoon (Smitsman & Cox, 2008). Task difficulty is compounded in *means–means*–ends tasks because the goal is so removed that multiple means must be employed to attain it (Santos, Rosati, Sproul, Spaulding, & Hauser, 2005). Multiple means may be implemented sequentially, as in using a short stick to rake in a longer stick, which could then be used to retrieve a distant toy, or in parallel, as in standing on a step stool while wielding a pole to reach a distant object (McGraw, 1935).

Typically, researchers study means–ends problem solving in infants by assessing their ability to use manual tools to retrieve an out-of-reach object and focusing on spatial relations between the actor, tool, and goal (e.g., Connolly & Dalgleish, 1989; Smitsman & Cox, 2008; Sommerville & Feldman, 2008; Steenbergen, van der Kamp, Smitsman, & Carson, 1997). A recent series of experiments took a different approach (Berger & Adolph, 2003; Berger, Adolph, & Lobo, 2005). The task involved the whole body, not just the hands, and we focused on means–means–ends problem solving rather than simple means–ends problem solving: To reach a goal at the other side of a deep precipice, infants had to recognize that a bridge could serve as a means for crossing and that a handrail could serve as a means for augmenting balance on narrow bridges. The spatial challenges of such bridge–

handrail tasks require that the various body parts be coordinated with the location of the relevant environmental supports.

The bridge–handrail task requires a parallel means–means–ends solution. The body simultaneously links multiple elements—the feet balanced on the bridge and the hands grasping the handrail—as means for crossing the precipice. Such parallel coordination poses special problems because monitoring the top and bottom of the body simultaneously takes months to develop. Eleven-month-old cruising infants, for example, do not monitor their feet moving along the ground at the same time that they monitor their hands holding onto furniture for balance (Adolph, Berger, & Leo, in press). Although cruisers can see and feel their feet approaching a precipice, with their hands gripping a sturdy handrail, they step over the brink and fall. In contrast, 16-month-old walkers modify their crossing strategies on medium-sized bridges by slowing down, taking smaller steps, and turning sideways. To cross narrow bridges, they hang onto a sturdy handrail to augment balance. When bridges are impossibly narrow but no handrail is available, infants refuse to cross (Berger & Adolph, 2003). With only a wobbly handrail, they enhance balance control by pulling backward on the wobbly rail like a mountain-climbing rope (Berger et al., 2005).

Current Study

The current study focused on the complex spatial problems involved in the development of means–means–ends problem solving. We examined infants' ability to perceive the spatial relations among actor, goal, and two means in a new bridge–handrails task. We challenged 16-month-olds to cross bridges of varying widths located at various distances from a handrail. Infants had to monitor whether their bodies fit on the bridge, whether they could reach the handrail with their hands while their feet were on the bridge, and whether modification of handrail-use or bridge-crossing strategies would enable safe crossing. By varying bridge–handrail proximity, infants had to cope with the spatial relation between the two means for crossing the precipice. We expected greater success on wider bridges and when the handrail was in appropriate proximity to the bridge. We predicted that infants would devise strategies for crossing the bridges, but on narrow bridges far from the handrail, crossing would be impossible.

Method

Participants and Procedure

Twenty-eight infants (13 boys) were recruited through a commercial mailing list of families living in the New York City area. All were 16 months old (± 1 week) and born at term; most were White and middle class. In a structured interview (Adolph, Vereijken, & Shrout, 2003), parents reported the 1st day that infants walked independently 10 ft across a room. Walking experience ranged from 25 to 175 days ($M = 104.36$ days). Infants received a souvenir for participating.

Figure 1 shows the wooden bridge–handrail apparatus with starting and finishing platforms flanking a large precipice (Berger & Adolph, 2003; Berger et al., 2005). A 16- or 36-cm-wide bridge spanned the precipice and could be quickly changed between trials. A handrail ran parallel to the bridge. The bridge was placed at one of three locations relative to the handrail: flush, middle, and far, with the nearest edge of the bridge 0, 20.5, or 40 cm from the edge of the handrail, respectively. Previous work suggested that most infants would not require a handrail on the 36-cm bridge but would on the 16-cm bridge.

After infants were acclimated to the walkway, each bridge was presented twice at each location for a total of 12 trials. Six presentation orders were counterbalanced across sex. Infants began trials standing upright on the starting platform. Trials ended when infants crossed, fell, or remained on the starting platform for 45 s. Trials were videotaped with side and overhead views mixed onto a single video frame. After testing on the walkway, an experimenter measured infants' height, weight, and arm span. Sessions lasted approximately 60 min.

Data Coding

Data were coded from videotapes using MacSHAPA, a computerized video coding system (OpenSHAPA.org; Sanderson et al., 1994). A primary coder scored 100% of trials. To ensure interrater reliability, a secondary coder scored 25% of each infant's trials. For categorical and frequency measures, we calculated the proportion of trials that the two coders were in agreement. Interrater reliability ranged from .97 to 1.0; p values for all Cohen's Kappa coefficients < .01. For measures of duration, we calculated the correlation between coders' scores. Correlation coefficients ranged from $r = .98$ to $r = 1.0$. Only 2% of reliability trials

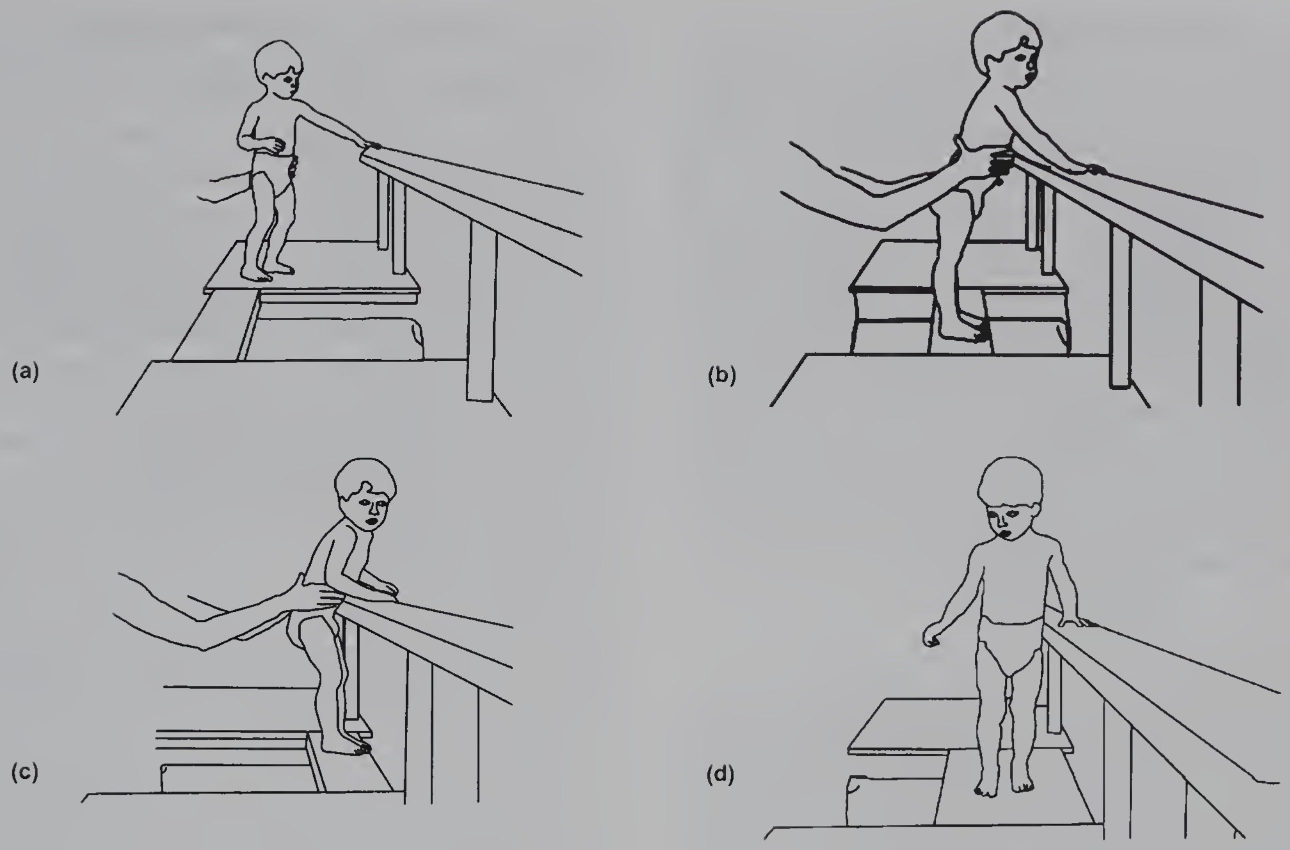

Figure 1. Walkway with varying bridge widths and handrail locations spanning a precipice (76.2 cm long × 76 cm wide × 74 cm deep) lined with 13.5 cm of foam padding along the sides and bottom. Apparatus is shown with (a–c) 16-cm and (d) 36-cm bridges at (a) far, (b) middle of the walkway, and (c,d) flush with the handrail locations.
Note. Caregivers (not shown) stood at the far end of the finishing platform (157 cm long × 76 cm wide × 86 cm high) and encouraged infants to cross by offering toys and cereal but did not draw infants' attention to the handrail or provide instructions. An experimenter (partially visible) followed alongside infants to ensure their safety. An assistant (not shown) adjusted the bridges and switched the handrails. To keep infants motivated, an easy, baseline 72-cm wide bridge was presented after each block of three trials.

resulted in discrepancies; these were resolved through discussion.

Crossing behaviors. Coders scored attempts to walk over the bridge (stepped onto the bridge with both feet) as successful if infants walked from one platform to the other without falling. Coders documented body position (facing forward, turned sideways) as infants stepped onto the bridge, whether they used the handrail (touched with ≥ 3 fingers for ≥ 0.5 s after stepping onto the bridge), and how they used the handrail (five combinations of body/arm positions). For successful attempts, coders measured number of steps to cross.

Exploration prior to embarking. Latency to step onto the bridge (from the moment that infants were released by the experimenter and faced the bridge or finishing platform until they stepped onto the bridge) included time spent in exploration and in displacement activities such as calling to the caregiver. Apparatus exploration included touching the handrail or bridge for ≥ 0.5 s before stepping onto the bridge. Exploration of the distance between bridge and handrail included shifting back and forth between bridge and handrail at least once in the same trial or gesturing toward the handrail by extending the arms while standing in front of the bridge.

Walking skill. To estimate infants' walking skill, average step length was calculated from videotape by dividing the distance between 2 points on the full walkway by the number of complete steps to walk from one point to the other.

Results

Attempts to cross, body position while crossing, and exploratory behaviors were analyzed with 2 (bridge width) × 3 (bridge location) repeated measures analyses of variance (ANOVAs). Main effects and interactions were followed by contrasts comparing each pair of locations for the two bridge widths and paired t tests comparing the two bridge widths at each of the three locations for a total of nine comparisons. A Bonferroni-adjusted alpha level corrected for experiment-wise error rates (overall $p = .05$).

Because so few infants attempted to cross the 16-cm bridge at the far location, we could not conduct repeated measures ANOVAs on infants' behaviors once they were on the bridge. Instead, we ran a series of planned comparisons for success rate, number of steps to cross the bridge, handrail use, and strategies for using the handrail.

Five children were missing either the 16-cm/middle or 36-cm/far width/location combination. These infants still received 12 trials total, but other trials were substituted due to experimenter error, for a total of 336 trials in the data set. Consequently, the number of participants included in repeated measures analyses was reduced from 28 to 23. The number of available trials was reduced for some measures because portions of trials were momentarily obscured from the camera view.

Crossing Behaviors

Infants attempted to walk over bridges on 72% of trials. An ANOVA on attempts to cross confirmed main effects for bridge width and bridge location (row A, Table 1; see Table 1 for all F and p values). Post hoc analyses revealed that infants attempted to cross the 36-cm bridge more often than the 16-cm bridge and attempts were less frequent when bridges were far from the handrail (all $ps \leq .03$; total height of bars in Figure 2a). Successful bridge crossings (striped regions in Figure 2a) were frequent on the 36-cm bridge at all locations but limited largely to the flush and middle locations on the 16-cm bridge (59% and 66% of attempts, respectively). Planned paired samples t tests on successful attempts revealed differences between the 16- and 36-cm bridges at all bridge locations (all $ps < .01$) and revealed that infants were more successful when the 16-cm bridge was at the middle than far location, $t(7) = 2.97$, $p < .03$.

Infants' modification of bridge-crossing and handrail-use strategies took into account the spatial relations between their bodies, the bridge, and the handrail. An ANOVA on proportion of trials that infants turned their bodies sideways to fit onto the bridge revealed main effects for bridge width and bridge location (row B, Table 1). Infants most frequently faced forward and put one foot in front of the other while crossing bridges (sparse striped and dotted regions of Figure 2a) but were likely to turn sideways, sliding one foot behind the other, when the bridge was narrow and when the bridge was in the flush or middle positions (dense striped and dotted regions of Figure 2a). At each location, infants walked forward on the 36-cm bridge more often than on the 16-cm bridge, all $ps < .05$. As with attempts and successes, infants also walked forward over the 16-cm bridge more often at the middle location than at the other locations (all $ps < .01$). We had assumed that the flush position would be most conducive for walking, and this was the arrangement in our previous studies. However, the narrow space of the flush position forced infants' bodies against the handrail and limited the number of effective whole-body solutions. The middle bridge location gave infants room to maneuver their bodies, leaving the handrail accessible.

On successful trials, infants took more steps to cross the 16-cm bridge than the 36-cm bridge at both middle and flush locations, all $ps < .01$ (Figure 2b). Only 3 infants successfully crossed the

Table 1
Main Effects and Interactions of Bridge Width and Handrail Location on Infants' Bridge-Crossing and Exploratory Behaviors

	Main effect width		Main effect location		Interaction width/location	
Outcome measure	*F*(*df*)	*p* value	*F*(*df*)	*p* value	*F*(*df*)	*p* value
Crossing behaviors

G. Gestures toward handrail	14.72(1, 22)	< .01	*ns*		3.83(2, 44)	< .03

Note. Effect size for all main effects with $p < .01 = .53$. Effect size for main effect with $p < .03 = .47$.

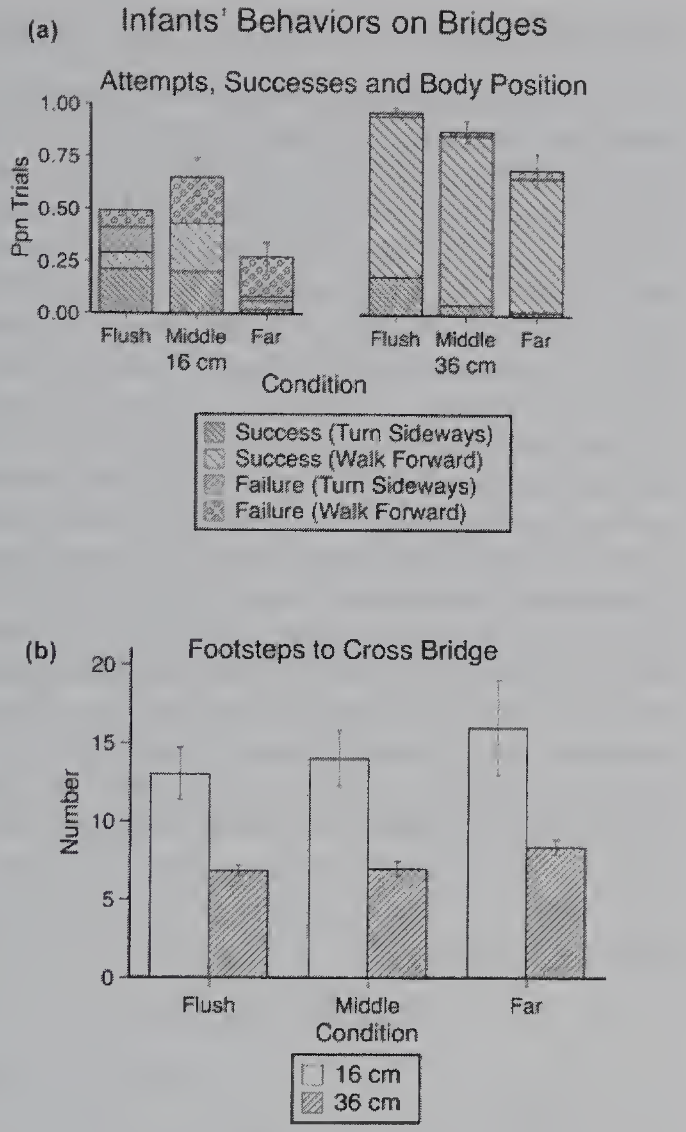

Figure 2. Effects of bridge width and bridge location on locomotor behaviors. (a) Proportion of trials infants attempted to walk, categorized by success and body position while crossing. (b) Number of footsteps infants took to walk over the bridge.
Note. Only 3 infants crossed the 16-cm bridge at the far location. Error bars denote standard errors.

16-cm bridge when it was far from the handrail, so analyses including that condition could not be performed. Location did not influence the number of steps to cross the 16-cm bridge. However, infants took more steps to cross the 36-cm bridge when it was far from the handrail than when it was flush with the handrail or in the middle of the walkway, $t(17) = 2.72$, $p = .01$ and $t(17) = 2.55$, $p = .02$, respectively.

Twenty-six infants used the handrail at least once. On the 90 trials when infants used the handrail, they held the handrail as they embarked or immediately after (within 2 s) stepping onto the bridge 65.6% of the time, suggesting that they coordinated both means in parallel prior to crossing. Planned paired-samples *t* tests confirmed that on attempted trials infants used the handrail more often on the 16-cm bridge than the 36-cm bridge when bridges were in the middle of the walkway, $t(17) = 10.31$, $p < .01$ (Figure 3). On the 16-cm bridge, infants never used the handrail at the far location. Handrail use at flush and middle locations did not differ. On the 36-cm bridge, only 1 child on one trial used the handrail at the far location. Surprisingly, infants used the handrail more often at the flush than middle and far locations, $t(26) = 8.37$, $p < .01$, and $t(18) = 7.51$, $p < .01$, respectively, even though touching was unnecessary (infants successfully crossed the 36-cm bridge without handrail use at the middle and far positions and in previous work; Berger & Adolph, 2003). Flush touches were cursory taps with one hand, as if noting rather than needing the handrail. When infants needed the handrail as a means for keeping balance, their touches were extended and they leaned toward the rail with their whole body.

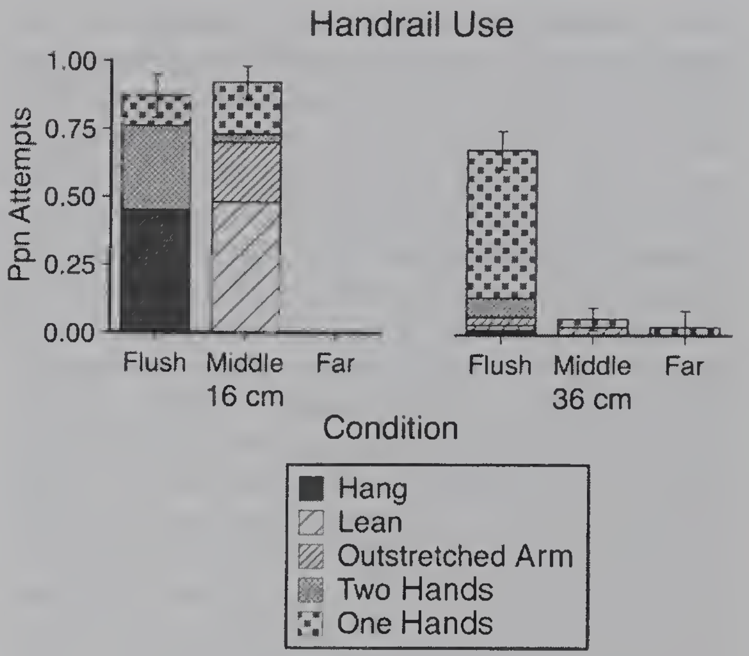

Figure 3. Proportion of attempted trials that infants used the handrail and their strategies for using the handrail at each bridge width/location combination.
Note. Infants could execute more than one type of strategy per trial but did not receive credit for performing the same strategy more than once per trial. Error bars denote standard errors.

Rates of handrail use were similar for the 16-cm flush, 16-cm middle, and 36-cm flush bridges, but infants displayed five qualitatively different strategies for coordinating placement of their hands on the handrail and their feet on the bridge, depending on bridge width and location. On half of the 16-cm flush trials, infants fit on the bridge by pressing the handrail against their chest and draping their bodies and arms over the railing (solid region in Figure 3 and illustrated in Figure 1c). On the other half, they used both hands to hold on as they walked sideways facing the handrail with their arms bent (dense checked region in Figure 3). On the 16-cm bridge in the middle of the walkway, infants turned their bodies sideways, leaned forward at the waist, and grabbed the handrail with two outstretched hands (sparse striped region in Figure 3 and illustrated in Figure 1b) or they walked forward with an arm fully outstretched to the side (dense striped region in Figure 3). In contrast, on the 36-cm bridge at the flush location, infants lightly touched the handrail with one hand as they walked (Figure 3 sparse checked region and illustrated in Figure 1d). The duration of infants' touches on the 16-cm flush (2.7 s) and 16-cm middle (2.85 s) bridges lasted over twice as long as they did on the 36-cm flush bridge (1.29 s), indicating that infants clung to the handrail on the 16-cm bridge but quickly tapped the 36-cm bridge as they passed. Thus, infants invented strategies for surmounting the distance between the bridge and handrail that were tailored to the width of the bridge and the distance from the handrail.

Exploration of Spatial Configuration Prior to Embarking

Infants engaged in a variety of information-gathering behaviors before deciding whether to cross the bridge. The ANOVA on latency to step onto the bridge confirmed main effects for bridge width and bridge location (row C, Table 1). Post hoc comparisons revealed longer latencies on the 16-cm bridge than on the 36-cm bridge and longer latencies at the far location than at the flush or middle locations (all *ps* < .03; Figure 4a).

Exploratory touching of the handrail and bridge decreased on the wider bridge and as the bridge moved farther from the handrail (rows D and E, Table 1; Figure 4b). The ANOVA for handrail exploration confirmed main effects for bridge width, bridge location, and an interaction between the two factors; the ANOVA for bridge exploration showed only a main effect for location. Post hoc comparisons revealed more exploration of the handrails on the 16-cm bridge than the 36-cm bridge at all locations (all *ps* < .04) and more bridge

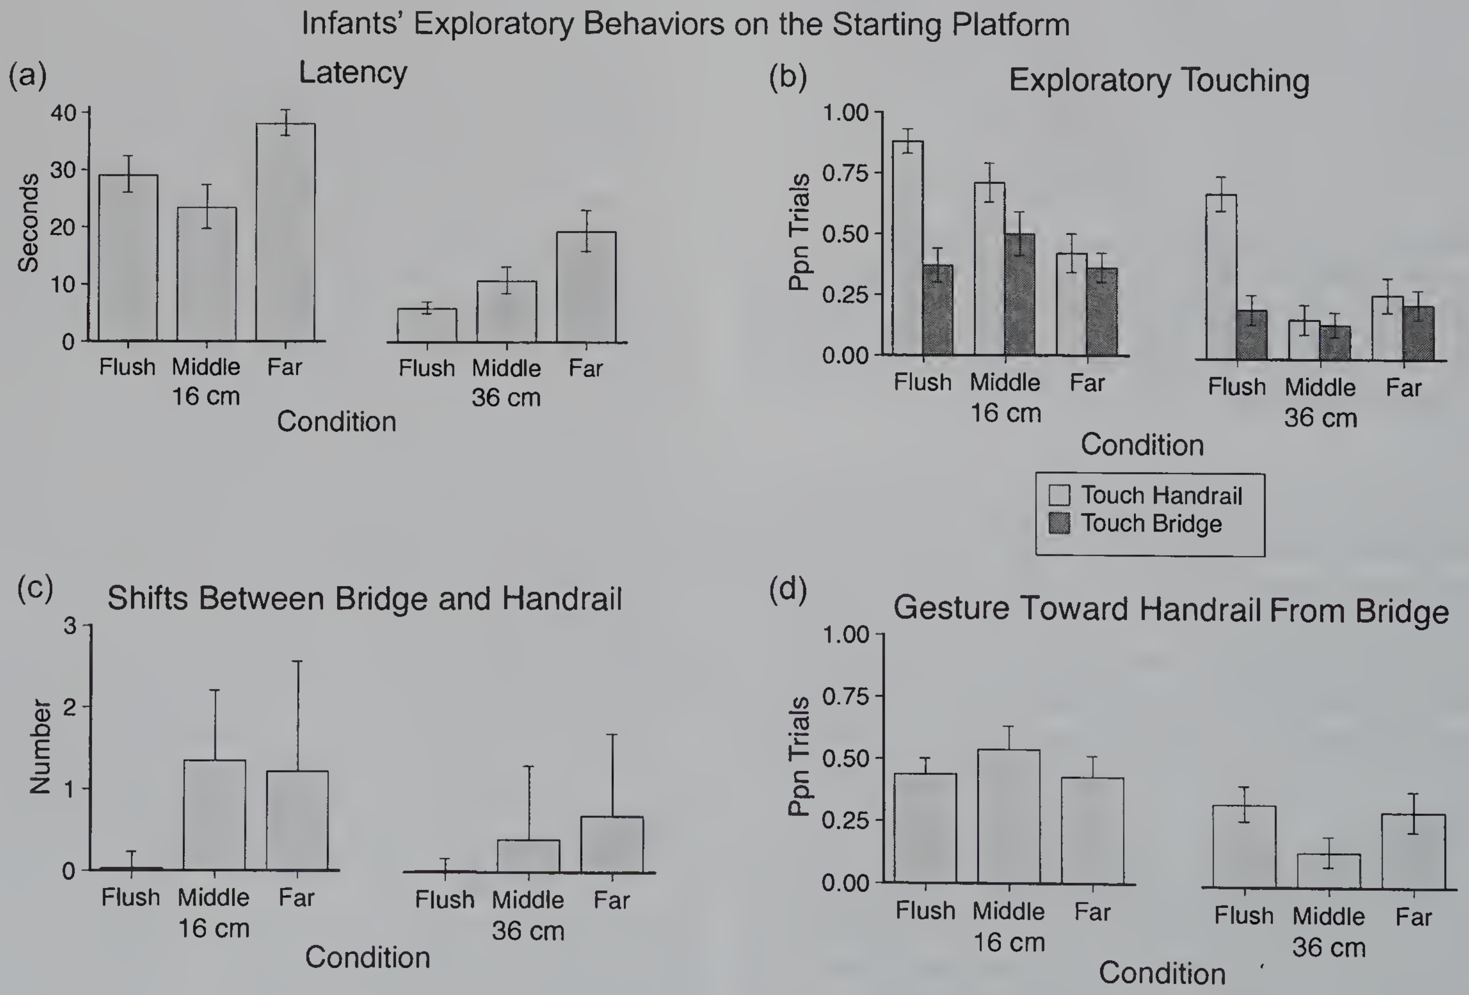

Figure 4. Effects of bridge width and bridge location relative to the handrail on exploratory behaviors. (a) Latencies to step onto the bridge. (b) Touching the handrail (light bars) and bridge (dark bars). Exploration of the distance between bridge and handrail by (c) shifting back and forth between the bridge and the handrail and (d) gesturing toward the handrail while standing at the bridge.
Note. Error bars denote standard errors.

exploration on the 16-cm middle location only, $t(22) = 3.85$, $p < .01$.

To gauge the distance between the bridge and handrail and decide whether and how their bodies could span the distance between the two means, infants shifted their bodies back and forth between the bridge and handrail while still on the starting platform (Figure 4c) and leaned their bodies or stretched out their arms toward the handrail when they were standing in front of the bridge (Figure 4d). ANOVAs on frequency of body shifts and gestures toward the handrail revealed main effects for bridge width and interactions between bridge width and bridge location (rows F and G, Table 1); the ANOVA on exploratory shifts also revealed a main effect for bridge location. Post hoc comparisons revealed that infants vacillated between the bridge and handrail more often on the 16-cm bridge than on the 36-cm bridge at both the middle and far locations, shifted more often at the middle and far locations than at the flush location on both bridge widths (all ps $< .03$), and gestured toward the handrail more often when the bridge was 16 cm than when it was 36 cm at the middle location, $t(22) = 4.03$, $p < .01$.

Individual Differences

On average, infants were 78.51 cm tall (range = 70.05–91.00 cm) and their mean arm span from fingertip to fingertip with arms outstretched was 81.69 cm (range = 76.20–88.45 cm). This means that the handrail fell at approximately elbow level and, in the far position, the handrail was beyond their reach unless they leaned nearly parallel to the ground. Infants' mean weight was 10.42 kg (range = 8.54–12.75 kg). Taller infants walked faster on baseline trials, $r(21) = -.51$, $p < .02$. Neither body dimensions nor days since walking onset were correlated with exploratory behaviors, attempts to cross the bridges, or success at crossing. However, infants' arm span was significantly correlated with handrail use. The longer their arms, the more likely they were to use the handrail, $r(23) = .42$, $p < .05$, and to carry out strategies for spanning the distance between the handrail and the bridge (leaning their bodies as they walked or walking with an arm outstretched to reach the handrail), $r(23) = .45$, $p = .03$.

Walking proficiency was related to performance on the bridges. The longer the distance between each footstep on baseline trials (an indication of mature gait), the shorter infants' latencies to step onto the bridge, $r(28) = -.46$, $p < .02$, the less likely they were to explore the distance between bridge and handrail, $r(28) = -.44$, $p < .02$, and the more likely they were to cross successfully, $r(28) = .47$, $p < .02$.

Handrail use and success were correlated with strategies for coping with the distance between the bridge and handrail. The more often infants gestured toward the handrail or shifted back and forth between the bridge and handrail on the starting platform, the more likely they were to use the handrail once on the bridge (Figure 1a; top panel Table 2). The more often infants leaned their bodies, stretched out their arms so that they could reach the handrail, turned their bodies sideways, or used both hands to hold onto the handrail when they were on the bridge, the more likely they were to cross successfully (bottom panel Table 2). For trials on the 16-cm bridge only, success was also related to whether infants used the handrail, $r(28) = .60$, $p < .01$.

Discussion

Means–Means–Ends Problem Solving

We examined infants' solutions to the localization problem of coordinating "multiple and mobile frames of reference" (Lockman, 2000, p. 140) in a whole-body, means–means–ends task. This work advanced previous studies of infants' problem solving in three ways. First, infants had to

Table 2

Correlations Between Infants' Exploration of Distance Strategies and Handrail Use After Embarking and Crossing Strategies and Success

Strategy type	Outcome measure	
	Use handrail	
Exploration of distance	*r(df)*	*p* value
Lean body or stretch arms toward handrail	.42(28)	< .03
Shift body between bridge and handrail	.41(28)	< .03
	Success	
Crossing strategy	*r(df)*	*p* value
Lean body	.55(28)	< .01
Walk with outstretched arms	.58(28)	< .01
Turn sideways on bridge	.71(28)	< .01
Use both hands to hold handrail	.69(28)	< .01

coordinate three key spatial relations on each trial—bridge and handrail, bridge and body, and handrail and body—rather than coordinate two frames of reference, such as object and surface or actor and tool (e.g., Bourgeois, Khawar, Neal, & Lockman, 2005). Second, infants had to monitor changes in spatial relations of the two means due to variations in bridge location. Third, with each step on the bridge, infants had to update their assessment of the spatial relations.

Sixteen-month-olds were active problem solvers. When infants attempted to cross narrow bridges, they juggled fitting their bodies onto the bridge, testing whether they needed a handrail to augment their balance, and orienting their bodies so that their upper extremities were securely on the handrail while their feet were firmly on the bridge. Infants viewed the bridge as a means for crossing the walkway, the handrail as a means for augmenting balance, and their own bodies as the link between the two. Failures were infrequent, suggesting that infants coordinated three simultaneously changing spatial relations. This finding is the first systematic demonstration of parallel coordination of multiple means in a problem-solving task in human infants.

Bridging the Gap: Understanding Spatial Relations

This experiment bridged the gap between research on spatial reasoning and studies of locomotor development. Typically, means–means–ends tasks require sequential implementation of means, such as using a knife to slice a lemon and then a reamer to squeeze out the juice. Alternatively, multiple means can be carried out in parallel, such as using salad servers to dole out a serving. Logically, infants would have to perceive a bridge as too narrow before considering whether a handrail was a viable means for augmenting balance. On wide bridges, infants ignore the handrail; they run straight across without touching the handrail (Berger & Adolph, 2003). However, once infants recognized a bridge as too narrow to serve as a sole means for crossing the precipice, they considered the spatial relations of the two means relative to each other and to themselves. Handrail and bridge-crossing strategies were highly sensitive to the spatial configuration of each condition. On most narrow bridge crossings, infants were already holding the rail as they stepped onto the bridge or grabbed onto it immediately after, indicating consideration of the two means in parallel, rather than in sequence, before going onto the bridge.

Previously (Berger et al., 2005), we postulated that implementing a means might lag behind recognizing a means because of a reported delay between the time toddlers choose the appropriate tool to solve a problem at about 21 months old and the time they actually use the tool to solve the problem at about 31 months old (Chen & Siegler, 2000). But this might not be true. Instead, success may result from the opportunity to devise clever, new solutions. Infants used their bodies to assess distance with the explicit purpose of determining whether the handrail and bridge in combination could be used as means to solve the problem. Infants devised new ways of using the handrail unobserved in previous bridge and handrail studies such as leaning forward while walking sideways (Figure 1b). Forcing infants to choose from a fixed set of behaviors determined by the experimenter and to use tools arranged inches from midline (e.g., Chen & Siegler, 2000; Smitsman & Cox, 2008) may artificially limit infants' ability to figure out the means to an end. In real life, tools may be at a great distance, and creativity is crucial for devising solutions to novel problems.

The suite of bridge–handrail studies showcases impressive problem solving in 16-month-old infants. Infants demonstrated knowledge about needing a suitable floor for crossing, about recruiting implements from the environment to enhance balance control, and about modifying typical locomotor strategies in response to ongoing challenges. The task for future research is to trace the developmental history beginning with cruising infants' first recognition that they can use a handrail as a means to support themselves to the sophisticated behaviors demonstrated by 16-month-olds as they solve means–means–ends problems.

What Paradox? Referential Cues Allow for Infant Use of Phonetic Detail in Word Learning

Christopher T. Fennell
University of Ottawa

Sandra R. Waxman
Northwestern University

Past research has uncovered a surprising paradox: Although 14-month-olds have exquisite phonetic discrimination skills (e.g., distinguishing [b] from [d]), they have difficulty using phonetic detail when mapping *novel* words to objects in laboratory tasks (confusing *bin* and *din*). While some have attributed infants' difficulty to immature word learning abilities, the hypothesis presented herein is that infants are powerful word learners and this apparent difficulty occurs only when the referential status of the novel word is unclear. Across 2 experiments, 14-month-old infants ($N = 44$) used phonetic detail to map novel words to objects when conditions were conducive to word-referent mapping (clear sentential contexts and word-referent training), thus revealing no fundamental discontinuity in its use from speech perception to word learning.

In their 1st year of life, infants become attuned to the speech sounds of their native language. Infants' initial sensitivity to a universal set of phonetic categories is shaped by experience with the ambient language. By their first birthdays, they refine their sensitivity to those phonetic categories that carry meaning in their native language (Kuhl et al., 2006; Werker & Tees, 1984). During this same developmental period, infants become increasingly proficient word learners. By 12 months, they have acquired dozens of words and produce at least a handful on their own (Fenson et al., 1994). By 14 months, infants begin to use not only the word itself but also the linguistic context in which it is presented as a cue to meaning. They identify novel words presented as count nouns (e.g., ''This is a toma'') and map them specifically to objects and object categories (Waxman & Booth, 2001).

Infants' early advances in speech perception and word learning are impressive, but recent investigations have uncovered a surprising paradox: Fourteen-month-old infants appear unable to effectively recruit their fine sensitivity to native language phonetic detail when mapping novel words to meaning (Pater, Stager, & Werker, 2004; Stager & Werker, 1997; Werker, Fennell, Corcoran, & Stager, 2002). Our goal in this article is to demonstrate that this paradox is apparent only: Infants successfully recruit phonetic detail in novel word–object mappings when it is clear that the word is intended to refer to the object.

To begin, we review the evidence for this apparent paradox. We focus primarily on 14-month-olds' performance in the Switch task (Werker, Cohen, Lloyd, Casasola, & Stager, 1998) because it is in this task that their failure to recruit phonetic detail in establishing word–object mappings has been revealed. Our review underscores the precision of the now-classic Switch task and its value in developmental research, but also brings to light an important caveat: There is nothing in the design of this task that makes it clear that the novel word involves reference.

In the Switch task, infants are first introduced to a novel word–object pairing. They hear a novel word, presented repeatedly, as they observe an image of a brightly colored novel object moving back and forth across a screen. This pairing continues until infants find it familiar, as indicated by a criterial decline in looking. In the subsequent test phase, infants witness two types of test trials, presented sequentially. On ''same'' trials, the original word–object pairing is preserved. On ''switch''

We thank J. Werker and E. Leddon for discussions, A. Weisleder and L. Plotkin for testing, and the participating parents and infants. NIH R01-HD30410 (S.W.) and a SSHRC Postdoctoral Fellowship (C.F.) provided research support.

trials, the pairing is disrupted: The object is paired with a different word. The logic is straightforward: If infants detect this disruption, they should look longer on "switch" than on "same" trials. However, when the two novel words are phonetically similar (e.g., *bin* vs. *din*), 14-month-olds fail to detect the mismatch (e.g., Stager & Werker, 1997).

Considerable attention has been devoted to identifying the source of 14-month-olds' surprising failure. It does not stem from a frank inability to connect novel words with novel objects in the Switch task. When the novel words are completely phonetically dissimilar (*lif* vs. *neem*), 14-month-olds detect the disruption readily. Neither does their failure stem from an inability to perceive the close contrast (e.g., *b* vs. *d*). When the very same contrast is presented within the context of a standard speech perception task, 14-month-olds' sensitivity is robust (Stager & Werker, 1997). If 14-month-olds can master the demands of the switch task and can also detect the relevant contrast, what accounts for their surprising difficulty? Some have proposed that infants' difficulty reflects a discontinuity between the perceptually-based *phonetic* representations that infants refine over the first year, and the more abstract *phonological* representations that are required to support word learning (Brown & Matthews, 1997). Recent investigations cast doubt on this interpretation, however, because infants as young as 11 months are sensitive to fine phonetic distinctions between *known* words (e.g., *ball* vs. *doll*; Swingley, 2005). This finding, coupled with the fact that infants successfully incorporate detailed acoustic-phonetic information in their representations of novel as well as familiar words (Fisher, Church, & Chambers, 2004) indicates that in principle, infants can bring their appreciation of phonetic detail to bear in word learning.

Why, then, do 14-month-olds fail to recruit their finely tuned phonetic sensitivities when mapping words to objects in the Switch task? This question is especially compelling in face of evidence that infants this age are spontaneously adding words to their lexicons in earnest (Fenson et al., 1994) and even use unstressed grammatical elements (determiners) as cues to meaning (e.g., Waxman, 1999). Thus far, efforts to address this paradoxical finding in the Switch task have appealed either to general difficulties associated with word learning (Werker & Fennell, 2004) or to a host of perceptual, attentional and memory factors (e.g., Rost & McMurray, 2009; Thiessen, 2007; Yoshida, Fennell, Swingley, & Werker, 2009).

We offer a different view. We propose that infants do indeed harness their phonetic sensitivities in word learning, but that their apparent failures to do so in previous work reflect the ambiguous referential status of the novel words. To appreciate this ambiguous status, notice that in all previous implementations of the Switch task, novel words were presented in isolation. While this ensured that the speech stimuli would be identical to those presented in standard speech perception tasks, presenting words in isolation can have adverse consequences with respect to word learning. First, infants process isolated words *less* efficiently than words presented within phrases (Fernald & Hurtado, 2006). Second, words rarely occur in isolation in naturally occurring speech (Aslin, Woodward, LaMendola, & Bever, 1996; Brent & Siskind, 2001). Finally, and perhaps most importantly for the purposes of establishing meaning, when words do appear in isolation in naturally occurring speech, they are rarely names for objects. Instead, isolated words tend to be proper names ("Daddy!"), commands ("Stop!") or exclamations ("Wow!"). Importantly, infants are sensitive to this state of affairs. When novel words are presented within naming phrases ("Look at the blick!"), infants readily map them to the objects with which they occur. But when the very same words are presented in isolation ("Look! Blick!"), infants fail to establish a word–object mapping (Fulkerson & Waxman, 2007; Namy & Waxman, 2000).

If 14-month-old infants' failure to use phonetic detail in the Switch task is indeed a consequence of the ambiguous referential status of words, then when referential status is clarified, infants should successfully recruit their finely tuned phonetic sensitivities to establish a word–object mapping. We designed two experiments to test this proposal. In both, we introduced 14-month-olds to the same words, objects, and methods used in previous work (Pater et al., 2004; Stager & Werker, 1997; Werker et al., 2002), but systematically manipulated the manner in which we introduced the novel words in order to increase or decrease the clarity of the word-referent mapping.

Experiment 1

In this experiment, we embedded novel words in typical naming phrases. Our choice of naming phrases was guided by evidence that 14-month-olds interpret novel words presented as count nouns as names for objects and object categories (Booth & Waxman, 2009; Waxman & Booth, 2001).

Method

Participants

Sixteen English-learning (> 80% exposure) healthy full-term infants from greater Chicago participated (M = 14.7 months, range = 13.5–15.5 months), primarily from Caucasian middle- to upper-middle-class families recruited via mailings. An additional 11 infants were excluded due to: restlessness (10) or parental interference (1).

Stimuli

The stimuli were nearly identical to those in previous work, except that the novel words were presented in naming phrases.

Auditory. We recorded an English-speaking female producing three novel CVC words (*bin*, *din*, *neem*) in infant-direct speech within the context of seven different introductory phrases: Look. It's the _____. There's the ______. Do you see the _____? Look at the _____. Where's the ____? Here's the ______. I like the _____. We ensured that infants could not rely upon subtle sound differences in the introductory phrases to discriminate the target words. We spliced the introductory phrases from the *neem* stimuli just before the determiner (e.g., "*Look at* | the neem."), copied them, and spliced the determiners and nouns from the *bin* and *din* sentences onto the copies. This resulted in sentences where the introductory phrases were identical, as indicated in italics: "*Look at* the neem!" "*Look at* the bin!" and "*Look at* the din!" One isolated exemplar of the novel word occurred at the beginning of each trial so that infants would hear the relevant phonetic information first; another exemplar occurred at the end. *Neem* phrases were used for pre- and posttests; *bin* and *din* phrases were used for habituation and test trials.

Visual. See Figure 1. The habituation object moved horizontally across the screen. The pre- and posttest object remained stationary, while its wheel rotated.

Procedure

See Figure 1. After parent(s) completed the MacArthur Bates Communicative Development Inventory (MCDI), the infant and one caregiver were escorted to a quiet room (3.12 × 3.89 m), lit by a shaded 60-Watt lamp situated to the left and slightly behind the infant. Visual stimuli were projected onto a screen surrounded by black cloth 1.93 m from the infant. Audio stimuli were delivered at 65 dB, ± 5 dB, over two speakers located below the screen. As a masking device, caregivers listened to music over headphones. Infants' looking times were monitored via a hidden digital videocamera. The experiment was administered with the Habit X program (Cohen, Atkinson, & Chaput, 2004). The experimenter, who wore headphones throughout the procedure, was blind to trial type. Each 20-s trial began when the infant fixated on an onscreen attention getter. To begin, infants were presented with a pretest trial, involving a waterwheel object and the *neem* phrases. The habituation phase commenced immediately thereafter and ended when the infant's looking time across a two-trial block decreased to 65% of the longest block, or after 24 habituation trials (mean length = 10.55 trials, 95 tokens; SD = 6.22, 55.98), after which the test phase began. The word used in habituation phrases (*bin*, *din*) and the presentation order of the test trials were counterbalanced. A posttest trial,

using dissimilar stimuli from habituation (the waterwheel–*neem* pairing), followed the test phase. Infants recovered from the last habituation block to this posttest in both Experiments 1 and 2 (all *p* values < .01), ensuring that infants were not fatigued or generally disinterested in the task. Using a frame-by-frame analysis (1 frame = 33.33 ms), two experienced coders, blind to condition assignment, scored infants' looking times (*r* > .95 in Experiments 1 and 2).

Results and Discussion

When the novel words were embedded within naming phrases, 14-month-olds successfully harnessed their finely tuned phonetic sensitivities to map that word to its intended referent. See Figure 2. Infants looked reliably longer on switch (*M* = 11.67 s, *SD* = 4.56) than on same (*M* = 9.46 s, *SD* = 3.88) trials, *t*(15) = 2.36, *p* = .03, *d* = 0.52.

Infants' success in this task is striking. In contrast to infants hearing isolated words, these infants had to parse the novel words from the continuous speech stream. Their success, even in the face of this more crowded perceptual space, suggests that embedding the novel words in phrases did indeed clarify their referential status for the infants. But could infants' success be attributed to something else? In continuous speech, each phoneme (e.g., *b*) is influenced by those surrounding it; the transitions between phonemes provide coarticulatory cues, to which infants as young as 5 months show sensitivity (Fowler, Best, & McRoberts, 1990). Perhaps by embedding novel words in phrases, we provided infants in Experiment 1 with coarticulatory cues (transitions between determiners and novel words) that were unavailable to infants hearing isolated words in previous versions of the Switch task. To discover whether infants' success in Experiment 1 could be attributed to this additional perceptual information or to the referential status of the novel words, we designed a second experiment.

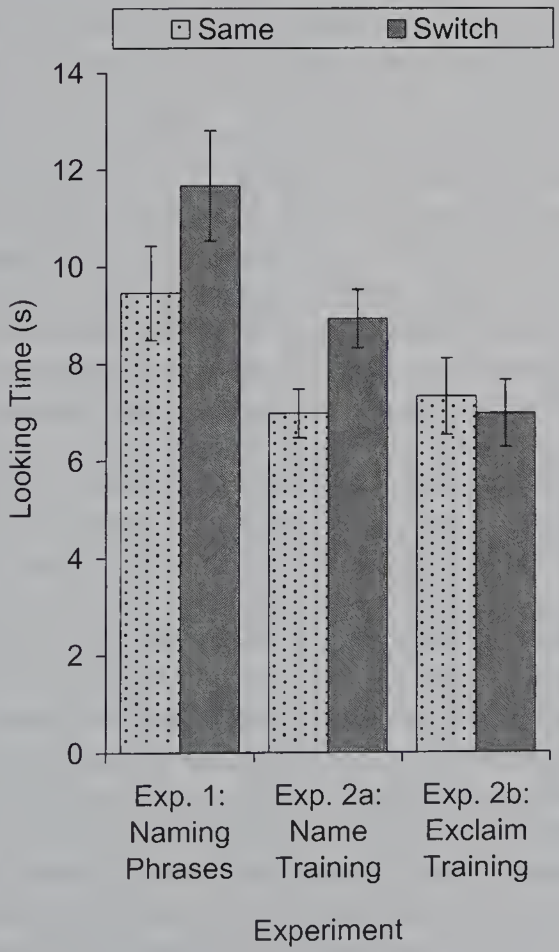

Figure 2. Mean looking times (and standard error) for same and switch trials across conditions.

Experiment 2

Our goal was to present the novel words in isolation, as in previous versions of the Switch task, but to maintain their referential clarity. To achieve this, we took advantage of a compelling finding: If infants first have an opportunity to observe a series of familiar objects (e.g., car, kitty), each paired with its familiar basic level name presented in isolation (e.g., "Car!" "Kitty!"), they subsequently map *novel* words, also presented in isolation, to novel objects. But if the very same familiar objects are initially paired with familiar exclamations (e.g., "Wow!" "Whee!"), infants fail to establish consistent mappings (Namy & Waxman, 2000).

Building upon this insight, we introduced a brief training period in which infants were introduced to three familiar objects (car, shoe, cat). Infants were randomly assigned to one of two training conditions. In the name-training condition, each training object (e.g., car) was paired with its familiar basic-level object name, presented in isolation (e.g., "Car!"). In the exclaim-training condition, each training object was paired with a familiar exclamation (e.g., "Wow!"). We then observed infants' performance in the Switch task, with novel words presented in isolation.

If infants' success in Experiment 1 can be attributed to perceptual factors (e.g., coarticulatory cues), then infants in both training conditions should fail to map the novel words, now presented in isolation, to the accompanying object in the subsequent Switch task. But if instead, infants' success in Experiment 1 is a consequence of increased referential clarity, then performance in the name- and exclaim-training conditions should differ. We predict that the name-training manipulation will establish that isolated words can refer to objects in the context of this task and that, as a result, infants in this condition will map the novel word in all its detail to the accompanying object. In contrast, although infants in the exclaim-training condition also hear familiar words, and although these words are themselves attention enhancing (e.g., ''Wow''), they do not refer specifically to objects. Therefore, we predict that infants in the exclaim-training will not infer that isolated words function as names for objects in this task and, as a result, will not map the novel word to the accompanying object in the subsequent Switch task.

Method

Participants

Twenty-eight English-learning, healthy, full-term infants (*M* = 14.37 months, range = 13.55–15.49 months) from greater Chicago participated. All infants comprehended the basic-level name for at least one training object, as measured by the MCDI. An additional 16 infants were excluded due to restlessness (8), comprehending none of the training object labels (5), technical error (1), or parental interference (2). There were no differences between the two conditions on any vocabulary measure (see Table 1).

Stimuli

The novel words, identical to those in Experiment 1, were now presented in isolation. The training phase included moving images of a car, cat and shoe with their basic-level names (*car*, *kitty*, *shoe*) or with familiar exclamations (*whee*, *wow*, *yay*).

Procedure

This was nearly identical to Experiment 1 with two exceptions (see Figure 1). First, in lieu of the pretest, we introduced a training phase: Infants saw three familiar objects, presented sequentially, each paired with either its appropriate basic-level name or an exclamation. The order in which these training trials were presented was counterbalanced across infants within training conditions. Second, because novel words were presented in isolation, habituation trials were reduced from 20 to 14 s in duration (similar to Stager & Werker, 1997).

Table 1
Experiment 2: Vocabulary Data

Vocabulary measures	Condition: Name	Condition: Exclaim	*t*(26)	*p*
Vocabulary: Comprehension	153.64	127.29	0.96	0.35
Vocabulary: Production	15.00	17.86	0.45	0.66
Training words comprehended	2.50	2.64	0.54	0.59
Training words produced	0.43	0.50	0.29	0.77

Results and Discussion

Even in the absence of any coarticulatory cues, infants in the name-training condition successfully established word–object mappings; those in the exclaim-training condition did not. A 2 (test trial: same vs. switch) by 2 (condition: name- vs. exclaim training) mixed analysis of variance revealed no main effects: trial, $F(1, 26) = 2.43$, $p = .13$, partial $\eta^2 = 0.08$, and condition, $F(1, 26) = 1.06$, $p = .31$, partial $\eta^2 = 0.04$. A significant Trial × Condition interaction, $F(1, 26) = 5.02$, $p = .03$, partial $\eta^2 = 0.16$, revealed the predicted outcome (Figure 2). Infants in the name-training condition established a word–object pair, looking reliably longer on switch ($M = 8.92$ s, $SD = 2.26$) than on same ($M = 6.97$ s, $SD = 1.87$) test trials, $t(15) = 2.53$, $p = .02$, $d = 0.94$. Thus, infants' use of fine phonetic detail in Experiment 1 cannot be attributed to low-level perceptual factors alone. In contrast, infants in the exclaim-training condition failed to detect the switch, $t(15) = 0.52$, $p = .61$, $d = 0.13$.

The difference between these two conditions cannot be attributed to selective adaptation, a phenomenon in which repeated exposure to one endpoint of a phonetic continuum (e.g., [b]) leads to a perceptual bias favouring the other endpoint (e.g., [d]). We tallied the number of habituation tokens (*bin* or *din*; 7 per trial) presented to infants in each of the conditions and found no significant difference (name: $M = 51$, $SD = 24.32$; exclaim: $M = 73$, $SD = 45.67$), $t(26) = -1.59$, $p = .12$, $d = -.60$. Furthermore, there was no correlation between this measure and infants' increased looking time to switch, $r(26) = 0.09$, $p = .66$. Moreover, an analysis of infants' vocabularies provided additional evidence that referential, and not perceptual, factors, accounted for infants' success. We tallied the number of training words comprehended by each infant (0–3), including those 5 infants who were excluded from the preceding analyses because they comprehended none of the training objet labels. This measure was correlated with success in the name-training condition, where comprehension was crucial to understanding that isolated words could refer to the objects, but not the exclaim-training condition: name, $r(16) = .59$, $p = .01$, and exclaim, $r(13) = -.24$, $p = .38$.

General Discussion

Together, these experiments constitute strong support for the hypothesis that 14-month-old infants can indeed recruit their finely honed sensitivities to phonetic detail in the task of word learning, and do so effectively when the referential status of the to-be-learned novel word is clear. When novel words are presented in an unambiguously referential context (naming phrases in Experiment 1; name training in Experiment 2), 14-month-olds recruit their perceptual sensitivities to establish precise word–object mappings. When the referential status of the novel word remains ambiguous (as in the original Switch tasks; Experiment 2: exclaim training), infants fail.

Moreover, these results take us one step further, demonstrating that infants have multiple ways to identify referential status. In Experiment 1, where the novel words were embedded in naming phrases, infants took advantage of syntactic cues to establish their referential status. In Experiment 2, where no syntactic information was provided, infants capitalized on pragmatic cues to establish referential status (Namy & Waxman, 2000). Infants in the name-training condition, who were provided with pragmatic evidence that words presented alone could indeed be names for objects, were able to exploit this evidence to map novel words to objects in the subsequent Switch task and to use fine phonetic detail in doing so. Importantly, infants' persistent failure to do so in the exclaim-training condition documents that simply presenting infants with familiar objects paired with familiar attention-directing words is not sufficient. Instead, what 14-month-old infants require to establish a word–object mapping is a reason to expect that the word is meant to refer. Although it is beyond the scope of the current article to consider fully the factors involved in infants' emerging understanding of reference (see Waxman & Gelman, 2009), it is clear that 14-month-old infants are sensitive to referential cues, that these support infants' establishment of word–object mappings, and permit infants to bring their finely honed phonetic sensitivities into play in the process of word learning. Thus, bringing in the notion of reference—a fundamental feature of human language—helps to resolve what was previously seen as a paradox in infant word learning.

Our proposal concerning the essential role of referential status also brings together a series of otherwise apparently unrelated recent findings under one umbrella rather than appealing to a diverse array of methodological and perceptual explanations. For example, when 14-month-olds are introduced to a novel object in the context of a focused, social interaction with an adult, they attend successfully to fine phonetic detail when establishing word–object mappings (Mani & Plunkett, 2008). We suspect that this animated social interaction, focusing specifically on an object for which infants had no known name, served to increase their interest in discovering its name. Similarly, when 14-month-olds are permitted to play with an unnamed novel object in their homes in the weeks preceding their lab visit, they attended to phonetic detail when mapping a novel word to that object in the lab during the Switch task (Fennell, 2004). Here, we suspect that infants' prolonged engagement with an unnamed toy augmented their interest in discovering its name when provided with candidates in the laboratory during the Switch task. Evidence from another recent report fits well with our focus on reference and meaning. When novel words were produced by a range of *different* speakers during habituation, 14-month-olds successfully detected changes in phonetic detail (Rost & McMurray, 2009). Rost and McMurray (2009) attributed infants' success to perceptual factors, hypothesizing that exposure to a range of exemplars supported infants' ability to build stable phonetic categories. We concur but point out that this task likely offered infants additional referential information as well. After all, when a range of different speakers consistently applies the very same word to a novel object, this social convergence signals that that word is the name of that object.

Another recent report indicates that clarifying referential status in the testing phase also aids infants. Yoshida et al. (2009) presented a version of the Switch task in which 14-month-old infants were introduced to two similar-sounding words (*bin* and *din*), each paired with a unique novel object. At test infants saw both novel objects simultaneously but heard only one of the two novel words. To succeed, infants had to map each of two similar-sounding words presented during habituation to its associated object and to represent these words with sufficient phonetic detail to direct their attention to the correct object at test. Surprisingly, 14-month-olds succeeded. Yoshida et al. argued that presenting the two novel objects simultaneously at test reduced the memory demands of the task, leading to infants' success. We take no issue with this interpretation but point to another design feature that was likely instrumental. To familiarize them with the forced-choice nature of this task, infants viewed ''filler trials'' before viewing the test trials themselves. The structure of the filler trials was nearly identical to that of the test trials, with one important exception: Filler trials included objects and words *familiar* to the infants (e.g., they saw a car and shoe side by side and heard *car*). In our view, these filler trials were instrumental not only because they oriented infants to the structure of the test trials but also because the inclusion of familiar words and objects, (like the name-training trails of Experiment 2) served to establish the referential status of novel words.

Each of these recent demonstrations, considered on its own, sheds light on a distinct factor mediating infants' performance. But invoking the notion of referential status provides a more integrative account for infants' patterns of successes and failures. In our view, these recent findings converge to support the proposal that infants use social, linguistic and pragmatic information as windows into the referential status of a novel word, and that once this status is assured, they recruit their sensitivity to fine phonetic detail to map that word to its intended referent.

Although we have focused expressly on the essential role of referential status in word learning, we acknowledge the importance of other elements as well, chief among them the perceptual factors. Recent evidence establishing the power of perceptual cues comes from Thiessen (2007). Before participating in a Switch task, infants in this experiment were exposed to a training period in which the novel words were presented under variable phonetic contexts. This purely perceptual boost in training supported infants' subsequent use of phonetic detail in the Switch task, suggesting that when the phonetic distinction is sufficiently robust (as with the completely distinct words *lif* and *neem*), 14-month-olds succeed (Werker et al., 1998). Infants' success in Thiessen (2007) and Werker et al. (1998) reveals that even in the absence of referential clarity, infants' attention to phonetic detail can be augmented by perceptual means. Importantly, the results of the current experiments reveal that the corollary is also true: Even in the absence of any added perceptual information, infants' attention to phonetic detail is boosted when the referential status of the word is made clear. In future work, it will be important to discover how various factors (perceptual, syntactic, social, and pragmatic) come together in the service of word learning.

The current work provides a resolution to what has been seen as a paradox. It reveals that there is considerable continuity in the phonetic representations that infants refine over the 1st year of life and the lexical representations they establish thereafter. It also fortifies the view that infants (like adults) take into consideration more than associations alone when establishing word meaning (Gogate & Bahrick, 1998; Waxman & Lidz, 2006). In every version of the Switch task, the presence of a novel word is correlated perfectly with the presence of a novel object. Yet this correlation alone, however perfect, is not sufficient to support the establishment of a strong enough word–object mapping to reveal infants' use of fine phonetic detail. We therefore conclude that when mapping words to meaning, infants recruit both their sensitivity to fine phonetic detail and their sensitivity to the distinct referential status of words.

Tolerance of Practices by Muslim Actors: An Integrative Social-Developmental Perspective

Maike Gieling, Jochem Thijs, and Maykel Verkuyten
Utrecht University

Using social-cognitive domain theory and social identity theory, tolerance judgments of practices by Muslim actors among Dutch adolescents (12–17) were investigated. The findings for Study 1 ($N = 180$) demonstrated that participants evaluated 4 practices using different types of reasons: personal, social-conventional, and moral. In Study 2 ($N = 970$), participants were more tolerant of acts considered to be a personal issue than of acts that pertained to moral issues (social-conventional acts were in the middle). Furthermore, participants were more tolerant of the particular practices than of campaigns for public support of co-Muslims for these practices. Level of education, in-group identification, and multiculturalism had much weaker effects in the moral than in the other domains. Age was negatively related to tolerance.

Islam has moved to the center of debates and politics in European countries and is at the heart of what is perceived as a ''crisis of multiculturalism'' (Modood & Ahmad, 2007; Zolberg & Long, 1999). The hotly debated issues are about concrete actions and behaviors. Should the practice of forced marriages among some Muslim groups be accepted? Should it be accepted that Muslim teachers refuse to shake hands with children's parents of the opposite sex? Should it be allowed that civil servants wear a headscarf and that students wear a burqa or a niqab? It is around these concrete questions that multiculturalism is put to the test and ways of life can collide. Studies on political thinking and behavior show that individuals tend to support democratic rights in the abstract but often do not endorse the same rights in concrete circumstances (see Vogt, 1997). It is one thing to endorse the freedom of speech and another thing to apply this freedom to, for example, an imam calling homosexuals inferior people.

The present article reports on two studies examining ethnic majority Dutch adolescents' tolerance of negatively evaluated practices by Muslim actors. Theoretically, the research aims to bring together social-cognitive domain theory (see Killen, Margie, & Sinno, 2006; Smetana, 1995; Turiel, 2002) and intergroup theories (see Nesdale, 2008; Tajfel & Turner, 1979). We examined tolerance judgments related to practices that evoke personal, social-conventional, and moral considerations and we studied the role of in-group identification and the endorsement of multiculturalism. Thus, we employed an integrative social-developmental perspective that considers social-psychological processes together with developments in cognitive knowledge and reasoning (Killen & McKown, 2005; Levy, West, & Ramirez, 2005; Pomerantz & Newman, 2000).

We conducted our research with ethnic majority Dutch participants between 12 and 17 years of age and we also examined the effects of age, gender, and level of education. In the Netherlands, the level of prejudice toward Muslims is relatively high among the general population and also among adolescents (Pew Global Project; Pew Research Center, 2005; Velasco Gonzalez, Verkuyten, Weesie, & Poppe, 2008). According to some commentators, there is an ongoing ''Dutch–Muslim'' cultural war and a related culture of fear (Scroggins, 2005; Vasta, 2007). Leading politicians have taken a fiercely negative position on Islam, which is defined as a backward religion that seriously threatens Dutch society, and national identity and culture (Verkuyten & Zaremba, 2005). Thus, our research examines tolerance in a rather negative intergroup setting.

Diversity and Diversity

There are different kinds of diversity and some are more problematic than others. For instance,

when people differ in their moral beliefs it is difficult to build a cohesive community. Take the example of the acceptance of homosexuality. The acceptance of homosexuality is a matter of personal opinion when one accepts it oneself but does not expect others to do so. It becomes conventionally regulated when one argues that everyone in one's own group or society should accept it but people in other groups or societies need not. But if one sees the acceptance of homosexuality as a moral issue one thinks that everyone else in all communities should support it, for example, as a basic human right. In that case, it becomes difficult to tolerate that others think differently.

This distinction is similar to the one proposed in social-cognitive domain theory (Killen, Margie, & Sinno, 2006; Smetana, 1995; Turiel, 2002). The social-cognitive domain model emphasized that children and adolescents apply different domains of knowledge in their social reasoning and judgments. Not only moral considerations (fairness, welfare, and rights) but also social-conventional (group norms and traditions) and personal ones (individual autonomy) are applied to a range of social events. Studies on children's social reasoning indicate that these domains emerge independently and simultaneously in early development (Kim & Turiel, 1996; Laupa & Turiel, 1993; Nucci, 2001). Children distinguish between them and react differently to personal considerations, conventional norms, and moral norms.

The distinction between these domains has been criticized because it would be cultural specific (Shweder, Mahapatra, & Miller, 1987). In addition, it has been argued that people often treat moral harms and injustices as merely conventional violations and sometimes react with moral outrage to what look like harmless violations of conventions (Kelly, Stich, Haley, Eng, & Fessler, 2007). However the domain theory claims that it is the personal, conventional, and moral distinction that appears at a young age and research has provided extensive cross-culture validation (see Turiel, 1998; Wainryb, 2006). Furthermore, because moral actions have intrinsic consequences for others' rights and welfare it is claimed that there is substantial cross-cultural agreement about what is moral, whereas there is more cultural variation in the content of conventional and personal issues. One implication is that the meaning of particular practices or behaviors is not always self-evident. The different interpretations of homosexuality mentioned earlier, is an example. Thus, to understand adolescents' differential judgments about various Muslim practices it should first be examined whether they make a distinction between these practices in terms of the personal, the conventional, and the moral domains.

Study 1 sets out to do this. We used four concrete cases of specific practices that are not illegal but that are hotly debated in Dutch society: the wearing of a headscarf by Muslim women, the refusal to shake hands with males by a female Muslim teacher, the founding of separate Islamic schools, and the public expression of the view that homosexuals are inferior people by an imam. These cases can reflect considerations that pertain to different domains at the same time and in that respect can be thought of as mixed-domain or multifaceted issues (Turiel, 1983, 1998). However, in comparison to each other, they are expected to differ in the relative salience of a particular type of domain that they evoke. For example, calling homosexuals inferior people can cause psychological harm to others because it is viewed as an attack on their way of being. This reflects moral considerations and could therefore be considered primarily a "moral" issue. No research has examined how individuals examine the wearing of a headscarf by a Muslim. The latter may be more likely to be considered a personal choice of the female herself given the apparent absence of harm to others or denial of resources (however, being denied the right to wear a headscarf may be viewed as "moral"). Not shaking hands with people from the opposite sex and the founding of Islamic schools were expected to be evaluated using predominantly social-conventional reasoning, as both deal with societal expectations. Thus, in Study 1 we predicted that adolescents will make a distinction between the four cases in terms of concerns predominantly raised by the three domains.

Subsequently, in Study 2 we examined whether tolerance judgments differ for the three domains. Specifically, following domain theory we expected adolescents to be less tolerant of practices that are perceived to violate a moral norm compared to social-conventional violations. In addition, practices that are evaluated negatively but considered as "personal" should be tolerated the most.

Practices and Social Support

Accepting that people hold dissenting beliefs does not have to imply that one tolerates the public expression of such beliefs or the actual practices based on such beliefs (Vogt, 1997). These dimensions of tolerance can trigger different levels of endorsement. In their study, Wainryb, Shaw, and Maianu (1998) found, for example, that European American children and early adolescents were more tolerant of dissenting speech than practices (see also Witenberg, 2002). Verkuyten and Slooter (2007) found that Dutch adolescents were more tolerant of Muslim parents publicly arguing for differential gender treatment or for a very light form of female circumcision than for the actual acts themselves. This higher acceptance of the public expression of the dissenting beliefs is consistent with the idea of free speech. It can be seen as stimulating debate that is important for the democratic process and as causing less direct harm or injustice than the actual acts. This means that it could be expected that adolescents are relatively more tolerant of public expressions of Muslim beliefs than of the actual practices based upon these beliefs.

However, this might depend on the intergroup context and the aim of the public expression. Specifically, Muslims trying to persuade cobelievers to engage in a dissenting practice can be perceived as a threat to the Dutch in-group. Ethnic majority Dutch adults and adolescents tend to see Muslims as threatening the Dutch way of life and this has been found to lead to strong negative and intolerant reactions (Van der Noll, Verkuyten, & Poppe, 2010; Velasco Gonzalez et al., 2008). Further, the Dutch majority tends to reject particular practices of Muslims and a recent nationwide survey showed that 50% of the Dutch consider the Western and Muslim way of life as opposites that do not go together (Gijsberts, 2005). In Study 2, the focus is not only on the participants' tolerance of the different practices but also on their acceptance of people trying to mobilize fellow Muslims. Participants were asked whether it should be allowed that the different Muslim actors campaign in order to try to convince others to do the same thing. This social mobilization of Muslims is typically seen as threatening to Dutch identity and culture (Sniderman & Hagendoorn, 2007; Velasco Gonzalez et al., 2008), and therefore the adolescents were expected to be less tolerant of Muslims campaigning for in-group support for the particular practice than of the actual practice itself.

In-Group Identification

Social identity theory (SIT; Tajfel & Turner, 1979) argues that individuals seek to belong to groups that provide them with a secure and positive social identity and are motivated to maintain positive distinctiveness through intergroup comparisons. Establishing favorable evaluative distinctiveness of one's group vis-à-vis other groups helps to achieve a positive group identity. However, negative out-group evaluation is by no means an automatic product of group distinctions, but a function, for example, of the extent to which children identify with their social group, the norms and beliefs held by the members of the child's social group, and the extent to which the out-group is perceived as threatening one's group in some way (Nesdale, 2008).

SIT interprets group identification in terms of individual differences in the degree to which psychologically central and valued group memberships develop. Some children are more inclined than others to see themselves as an ethnic group member and to value their ethnic group membership. Children who feel highly committed to their group are inclined to act in terms of their group membership. The theory argues that group identification interacts with out-group threat to predict out-group evaluation and tolerance of minority practices. The idea is that perceived threat has different effects depending on in-group identification because the motivational meanings of perceived threat are different. Compared to low identifiers, those with high in-group identification are more likely to be concerned about their group, especially when the position and value of the group identity are at stake. For example, high identifiers have been found to react more negatively toward the out-group under threat than do low identifiers (e.g., Bizman & Yinon, 2001; Tausch, Tam, Hewstone, Kentworthy, & Cairns, 2007). Thus, we expected that Dutch adolescents who feel strongly committed to their group will be less tolerant of Muslim practices compared to adolescents with relatively low in-group identification. In addition, we examined whether group identification equally affects tolerance judgments in the personal, the conventional, and the moral domain. Abrams, Rutland, Ferrell, and Pelletier (2008) found that children who identified more with their group showed in-group favoritism for conventional-based judgments but less so for morality-based judgments. Moral criteria are general and apply to in-group and to out-group behavior. Therefore, they should not be affected strongly by in-group identification. Thus, in Study 2, we expected higher in-group identifiers to be less tolerant of the practices and of social mobilization than lower identifiers, for acts that are considered more personal and social-conventional, but not for acts that raise moral concerns.

Multiculturalism

Individuals differ in the extent to which they endorse and value diversity within a society. A multicultural ideology entails "the general and fundamental view that cultural diversity is good for a society and for its individual members and that diversity should be shared and accommodated in an equitable way" (Berry, 2006, p. 728). Experimental research has shown that participants exposed to a message that endorses multicultural recognition show more positive out-group attitudes than those exposed to a message that supports a color-blind or assimilationist perspective (e.g., Verkuyten, 2005; Wolsko, Park, Judd, & Wittenbrink, 2000). Furthermore, and in relation to Muslims in the Netherlands, multiculturalism seems to provide a general ideological view about the importance of cultural diversity that reduces a sense of group threat. It also emphasizes that minorities should be recognized and valued in their group identity, and that there should be equal opportunities and rights (Van der Noll et al., 2010; Velasco Gonzalez et al., 2008). Therefore, we expected in Study 2 a positive association between the endorsement of multiculturalism and tolerance. In addition, we expected this association for the practices in the personal and the social-conventional domain but, again, not in the moral domain. The endorsement of cultural diversity is much more difficult when it concerns issues of harm, justice, and fairness.

Age, Education, and Gender

Although several studies have described a developmental progression from a generally intolerant attitude during the childhood years to increasingly tolerant judgments during adolescence (e.g., Bobo & Licardi, 1989; Enright & Lapsley, 1981; Enright, Lapsley, Franklin, & Steuck, 1984), different aspects of tolerance and domains of dissenting beliefs and practices are not taken into account in this research. Studies that do examine these different aspects present a more complex picture of age differences with tolerance and intolerance coexisting at all ages (e.g., Verkuyten & Slooter, 2007; Wainryb, Shaw, Laupa, & Smith, 2001; Wainryb et al., 1998). In contrast to young children, (early) adolescents tend to make more context-sensitive judgments about freedoms and rights. Thus, with age, concepts of rights and freedoms are increasingly evaluated in relation to other considerations and concerns, including the intergroup context (e.g., Helwig, 1995, 1997; Ruck, Abramovitch, & Keating, 1998). For Study 2, this might mean that older adolescents are less tolerant because they are more aware of the public debate about the Islamization of Dutch society. Lesser tolerance among older adolescents should exist for the social-conventional domain in particular, but not as clearly for the moral domain.

Chronological age is often used as an indicator for the level of cognitive and moral development. Age differences are typically interpreted in terms of increased cognitive skills and knowledge. The importance of these factors in explaining tolerance judgments is also suggested by the positive association between education and different forms of tolerance. In his review, Vogt (1997) concludes that there is clear evidence that education increases tolerance. Both the number of years of education and the level of education seem to contribute to this. In Study 2, and in addition to age, we examined the level of education. It was expected that a higher level of education has a positive effect on tolerance, but, again, less so for tolerance in the moral domain.

Several studies have found gender differences in tolerant judgments. For example, Killen, Sinno, and Margie (2007) showed that boys compared to girls more often found ethnic and racial exclusion acceptable. Verkuyten and Slooter (2007) also reported gender differences, with male adolescent being less tolerant than females. However, other studies using cognitive domain theory have found few gender differences (Smetana, 2006) or no differences at all (e.g., Helwig, 1995, 1997; Sigelman & Toebben, 1992). In Study 2, we explored possible gender differences in tolerance of Muslim practices.

Summary

The main purpose of this research was to examine tolerance of practices by Muslim actors among Dutch adolescents by applying social-cognitive domain theory to an intergroup context as has been done in prior research (Abrams et al., 2008; Killen et al., 2007). The novel approach taken in this study is to examine social reasoning together with group identity and the endorsement of multiculturalism in the Dutch–Muslim context, and to focus on aspects of tolerance regarding societally controversial Muslim practices. We focused on concrete cases that are debated in Dutch society and reflect different aspects of tolerance. In Study 1, we first examined empirically whether these cases can be distinguished in referring predominantly to personal, social-conventional, and moral concerns and considerations. In Study 2, we examined tolerance judgments in relation to these three domains and to in-group identification and the endorsement of multiculturalism.

Study 1

The purpose of the first study was to examine the type of concerns and considerations that are evoked by the different Muslim practices. Based on national public debates in the media, we first developed eight short descriptions of controversial cases involving Muslim actors. In a small pilot study, these eight cases were discussed with 10 adolescents. Four of the eight cases were found to be evaluated rather negatively and thus raised questions of tolerance (Vogt, 1997). These four cases reflected aspects of each social domain: the personal, the social-conventional, and the moral. Thus, we used these four cases and examined among a larger sample whether these cases did indeed indicate the three domains.

Method

Participants

The sample included 180 ethnically Dutch participants (''White'' majority and non-Muslim) between 12 and 17 years of age ($M = 14.12$, $SD = 1.73$). In total, 43% were males and 57% were females. Of the participants, 11.7% were in the lowest level of secondary education (junior vocational track), 18.3% in the middle level (higher vocational track), and 33.3% in the highest level of education (pre-university track). An additional 30% of the participants were in a mixed middle/higher level track. The pupils participated on a voluntary basis and the anonymous paper-and-pencil questionnaire was administered during regular class hours and under supervision.

Measures

The participants were asked to judge four different cases. The four cases involved: (a) the wearing of a headscarf (''Imagine that a group of students in your school wears a headscarf which covers a small part of the face''), (b) not shaking hands with someone of the opposite sex (''Recently, there has been a discussion about a female Muslim teacher who does not want to shake hands with men, such as colleagues and fathers of students''), (c) the founding of separate Muslim schools (''Some parents are founding Islamic schools where only Muslim children are accepted''), and (d) the voicing of harmful opinions about homosexuals (''Recently, an imam held a speech in a mosque in which he calls homosexuals inferior people''). The first case was expected to be predominantly considered a personal matter, the second and third were expected to mainly raise social-conventional concerns, and the fourth was expected to be considered a violation of a moral norm.

Modifications of standard social domain assessments were applied in this study to measure participants' interpretation of each case (see Smetana, 2006, for standard assessments). We investigated the type of judgments along three dimensions, each reflecting a different aspect of the conventional, the personal, and the moral domains, respectively. The first dimension entailed the extent to which the act is regarded as unconventional, and the second assessed whether the act is under personal jurisdiction of the actor (a criterion for the personal domain). The third dimension involved intrinsic harmful consequences for others, which is a justification category for using the moral domain (Smetana, 2006; Turiel, 1983). In addition, we included a question on the perceived wrongness of the act. Wrongness and domain type are conceptually independent, but moral transgressions tend to be perceived as more wrong than social-conventional violations (Smetana, 2006; Tisak & Turiel, 1988). Hence, wrongness ratings may be used to obtain additional support for the notion that an act elicits moral concerns.

For each case, the questions had the same response format. With respect to the issue of the headscarf, for example, students had to answer the following four questions: ''Is it inappropriate to wear headscarves in Dutch schools?'' (unconventional), ''Is it a personal decision to wear a headscarf?'' (personal), ''Are other people in school in any way harmed by it?'' (harmful consequences), and ''Is it wrong to wear a headscarf?'' (wrongness). The harmful consequences measure had a 5-point scale with answers ranging from −2 (*not at all*) to 2 (*very much*). The other measures were 7-point scales ranging from −3 (*no*) to 3 (*yes*).

Results

Both relative and absolute criteria were used to examine whether students assessed the four cases differently. First, for each separate judgment and for each case, we calculated the percentages of agreeing and disagreeing participants, and we conducted *t* tests to examine whether mean scores exceeded the neutral scale midpoint. Next, to test whether the scores on each of the dimensions differed between the practices, we conducted four separate repeated measures analyses of variance (ANOVAs), with the type of practice as the repeated measures factor. Results are shown in Table 1.

The absolute criteria revealed that all cases were generally considered as nonconventional. The mean scores on the nonconventional dimension were significantly higher than zero, and the majority of participants selected answers on the positive side of the scale. Yet, the ANOVA revealed a significant main effect of type of practice which indicated that some cases were considered more nonconventional than others, $F(3, 483) = 50.769$, $p < .001$, $\eta_p^2 = .24$. Pairwise comparison (LSD) showed that this was most strongly the case for the refusal to shake hands with someone of the opposite sex, followed by the imam's speech. The founding of Islamic schools and the wearing of a headscarf scored the lowest on the nonconventional dimension.

Mean scores and (dis)agreement percentages for the personal dimension revealed that the wearing of a headscarf was clearly considered a matter of personal choice, whereas the founding of Islamic schools and the voicing of harmful opinions about homosexuals were clearly not. Students were "undecided" about the refusal to shake hands. ANOVA results were consistent with this pattern, $F(3, 486) = 23.79$, $p < .001$, $\eta_p^2 = .13$.

Table 1
Mean Scores and Percentage Agreement for Judgment Dimensions by Case: Study 1

Dimension	Headscarf	School	Hand	Speech
Nonconventional				
M (*SD*)	0.62 $(1.88)^{**}_{a}$	0.93 $(1.68)^{**}_{a}$	2.33 $(1.13)^{**}_{c}$	2.01 $(1.56)^{**}_{b}$
% agree	53.5	59.2	91.0	81.0
% disagree	22.9	20.7	1.8	6.7
Personal				
M (*SD*)	1.01 $(2.02)^{**}_{a}$	−0.51 $(2.01)^{**}_{c}$	0.15 $(2.11)_{b}$	−0.46 $(2.25)^{*}_{c}$
% agree	62.8	29.3	41.2	31.3
% disagree	26.2	55.7	42.9	54.6
Harmful consequences				
M (*SD*)	−0.34 $(1.26)^{**}_{a}$	−0.45 $(1.06)^{**}_{a}$	0.22 $(1.27)^{*}_{b}$	1.43 $(0.82)^{**}_{c}$
% agree	31.6	16.3	47.2	88.2
% disagree	45.0	43.0	24.5	1.9
Wrongness				
M (*SD*)	−1.27 $(1.79)^{**}_{a}$	−0.14 $(2.05)_{b}$	−0.11 $(2.17)_{b}$	1.83 $(1.68)^{**}_{c}$
% agree	14.6	37.4	46.1	79.1
% disagree	62.6	42.0	38.9	9.8

Note. Means in the same row with different subscripts differ significantly at $p < .01$ by the Fisher least significant difference test.
$^{*}p < .05$. $^{**}p < .01$.

For the dimension of "harmful consequences," the mean scores suggest a distinction between the cases of the headscarf and school founding, on the one hand, and the cases of the handshaking and the imam's speech, on the other. The former cases were generally perceived as rather inconsequential, but the latter were considered to have a clear negative impact on others. However, this result is qualified by the (dis)agreement percentages and the ANOVA results, $F(3, 477) = 116.47$, $p < .001$, $\eta_p^2 = .42$. Although the score for the shaking of hands is above the scale midpoint, a minority of the respondents agreed that this practice has harmful consequences for others. Moreover, the mean score was significantly lower than that for the imam's speech ($p < .01$).

The results for "wrongness" indicate that participants clearly considered the speech against homosexuals as wrong, and the wearing of a headscarf as not wrong. Participants had a relatively neutral position in relation to the founding of Islamic schools and for the not shaking of hands. This pattern was confirmed by the ANOVA result, $F(3, 486) = 93.10$, $p < .001$, $\eta_p^2 = .37$.

To examine whether the scores for the dimensions were related to or qualified by age, education, and gender, we performed the same four ANOVAs with age included as a covariate and education and gender as factors. No significant main or interaction effects for these variables were found.

Discussion

The results of Study 1 revealed that participants differentiated between the four cases in terms of their ratings and responses, which reflected aspects of the personal, social-conventional, and moral domains. It is important to note that all practices were considered as nonconventional in the Netherlands. However, this does not mean that they exclusively evoked social-conventional concerns. As expected, the wearing of a headscarf was predominantly seen as an individual decision and a matter of personal choice. It was clearly not regarded as wrong or harmful for others. Both the not shaking of hands and the founding of Islamic schools were expected to be predominantly considered as social-conventional issues. The findings support this proposition. The majority of participants indicated that both practices were inappropriate in the Netherlands, whereas they did *not* judge them as being up to the actors, as having harmful consequences, or as being plainly wrong. Finally, the findings strongly support the idea that the imam's speech was predominantly considered a violation of moral norms. The majority of participants considered it wrong and harmful to make derogatory comments about homosexuals, and they clearly thought of it as a nonpersonal matter. Together, the findings provide support for the notion that these four cases tend to differ in the salience of the type of domains of sociomoral reasoning they evoke. To better understand participants' conceptualizations of these events, further analyses are required. In Study 2, we used these cases to examine tolerant judgments for the three domains and to test our hypotheses.

Study 2

The second study aimed to test four different hypotheses. First, participants were expected to be the least tolerant of the practice that for adolescents most strongly violates a moral norm (speech about homosexuals), followed by practices that predominantly violate conventional norms (the not shaking of hands and the founding of Islamic schools), and the most tolerant of the practice that relates most clearly to personal autonomy (the wearing of the headscarf). Next, it was expected that participants will be less tolerant of campaigns for the social support of fellow Muslims than of the actual practices themselves. Third, higher in-group identification was expected to be associated with less tolerance, whereas stronger endorsement of multiculturalism was expected to be associated with more tolerance. These two relationships were predicted for the practices that evoke personal and social-conventional considerations but not for the practice that is considered a moral transgression. Finally, we expected older adolescents to be less tolerant than younger ones, and we expected higher educated participants to be more tolerant. Again, these associations for age and education were expected to be weaker for the moral domain. In addition to testing these hypotheses, we explored the role of gender.

Method

Participants

This sample included 970 participants between 13 and 17 years of age ($M = 15.10$, $SD = 0.95$). In total, 51% were males and 49% were females. Of the participants, 36.3% were in the lowest level of secondary education (junior vocational track), 34.5% in the middle level (higher vocational track), and 29.2% in the highest level of education (pre-university track). At all three levels of education, all age groups participated. Thus, age and education were not confounded. Table 2 contains a breakdown of the sample by age, educational level, and gender. Both parents of the participants were ethnically Dutch ("White" majority and non-Muslim). The pupils participated on a voluntary basis and the anonymous paper-and-pencil questionnaire was administered in separate class sessions and under supervision.

Measures

The overall purpose of this study was to examine the contextual nature of adolescents' judgments about practices by Muslims. Therefore, two types of tolerance questions were used and because these two types of tolerance judgments have been found to be relatively independent (Verkuyten & Slooter, 2007), the measures were not counterbalanced but given in a fixed order. In order to measure the tolerance toward Muslim practices, the participants were asked to judge the four cases that were presented as follows: "Some parents are founding Islamic schools where only Muslim children are accepted. What should the government do about such schools?" "Imagine that a group of students in your school wears a headscarf which covers a small part of the face. What do you think the school should do?" "Recently, there has been a discussion about a female Muslim teacher who does not want to shake hands with men, such as colleagues and fathers of students. What do you think the school should do?" and "Recently, an imam held a speech

Table 2
Number of Respondents by Age, Educational Level, and Gender

Age group (years)	Educational level	Boys (%)	Girls (%)
13–14	Low	75 (7.7)	52 (5.4)
	Middle	21 (2.2)	24 (2.5)
	High	28 (2.9)	30 (3.1)
15	Low	66 (6.8)	54 (5.6)
	Middle	58 (6.0)	87 (9.0)
	High	85 (8.8)	88 (9.1)
16–17	Low	49 (5.1)	56 (5.8)
	Middle	86 (8.9)	59 (6.1)
	High	27 (2.8)	25 (2.6)

in a mosque in which he calls homosexuals inferior people. What do you think the mosque committee should do?''

In each case, there were four response categories: (a) ''Do nothing and allow it''; (b) ''Try to convince them [not to found those schools, not to wear a headscarf, to shake hands, to convince the imam to apologize], but allow it if they do not agree''; (c) ''Try to convince them not to do it, but forbid it if they do not agree''; and (d)''Simply not allow it.'' Items were recoded such that a higher score reflects a more tolerant attitude. In addition, to measure social support, the participants were asked if it should be allowed that the actors (i.e., the parents, students, teacher, imam) persuade other Muslims to engage in the same practice. Answers categories ranged from *definitely not allow it* (1), *to definitely allow it* (5). For each case, participants were also asked to rate their feelings toward the actors on a 7-point scale, ranging from *negative* (–3) to *positive* (3).

To measure *in-group identification*, participants were asked for their agreement with six different statements that have been used in various studies in the Netherlands (see Verkuyten, 2005). Three sample items are, ''My ethnic identity is an important part of myself,'' ''I strongly identify with my ethnic group,'' and ''I am proud of my ethnic background.'' Answers could range from *totally disagree* (1) to *totally agree* (5). Cronbach's alpha for the six items is .86. A higher score indicates stronger in-group identification.

The *endorsement of multiculturalism* was measured with eight items taken from Berry and Kalin's (1995) Multicultural Ideology Scale. These items have been used in previous research in the Netherlands (Arends-Tóth & van de Vijver, 2003; Verkuyten, 2006). Three sample items are: ''The more cultures there are, the better it is for the Netherlands,'' ''Immigrants in the Netherlands should forget their cultural background as soon as possible'' (reverse scored), and ''Migrants should be supported in their attempts to preserve their own cultural heritage in the Netherlands.'' Answers were given on 5-point rating scales: *strongly disagree* (1) to *strongly agree* (5). Cronbach's alpha is .81 and a higher score indicates a stronger endorsement of multiculturalism.

Analyses

The results are presented in three sections. The first section focuses on the tolerance judgments for the four cases, and the role of age, educational level, and gender. The second part describes differences for the two types of tolerance judgments, that is, tolerance of the practice itself and tolerance of the attempt to persuade others. The last section focuses on the effects of in-group identification and multiculturalism.

The concept of tolerance as we use it here implies forbearance or the putting up with something that one disapproves of or is prejudiced against (Vogt, 1997). Thus, in a preliminary analysis we first examined whether participants in general felt negative about the four practices. This turned out to be the case. Across the four cases, the average score lies well below the neutral midpoint (0) of the 7-point scales. One-sample t tests indicated that for each practice, the scores were significantly below zero, $ps < .001$, and even below −1, $ps < .001$. Thus, there were very few participants who indicated to have positive feelings and in general most participants in this sample were negative about the practices of the Muslim actors.

Results

Practices, Age, Education, and Gender

Tolerance judgments were expected to be dependent on the particular domain. We hypothesized that participants will be most tolerant of behavior that concerned mostly the personal choices of actors, and the least tolerant of moral violations. To examine these hypotheses, we first performed repeated measures ANOVA with type of practice as repeated measure. Next, we examined whether the pattern of tolerance judgments depended on students' educational level, gender, and age, by conducting 4 (type of practice) × 2 (gender) × 3 (educational level) repeated measures ANOVAs including age as a covariate, and type of practice again as the repeated measure. These analyses were conducted separately for tolerance of the actual practices and for tolerance of persuading fellow Muslims.

Tolerance of practices. The first ANOVA yielded a significant effect for type of practice, $F(3, 486) = 93.10$, $p < .001$, $\eta_p^2 = .37$. In agreement with expectations and the findings of Study 1, pairwise comparison (LSD) indicated that the level of tolerance was highest for the wearing of a headscarf ($M = 2.33$, $SD = 0.98$) and lowest for the imam's speech in which homosexuals are called inferior people ($M = 1.99$, $SD = 0.85$). In between these two were the social-conventional cases of the schools ($M = 2.16$, $SD = 0.94$) and the shaking of hands

($M = 2.20$, $SD = 0.95$). No significant differences between these latter two practices were found. Thus, tolerance was highest for the practice generally perceived as a personal decision, followed by the predominantly nonconventional practices, and lowest for the practice that was most clearly considered to be morally wrong. However, the second ANOVA revealed that the overall pattern was qualified by significant interactions with educational level, $F(6, 2856) = 3.92$, $p = .001$, $\eta_p^2 = .01$; gender, $F(3, 2856) = 13.06$, $p < .001$, $\eta_p^2 = .01$; and age, $F(3, 2856) = 2.75$, $p < .05$, $\eta_p^2 = .003$. These variables had significant main effects as well, $F(2, 952) = 7.23$, $p < .001$, $\eta_p^2 = .02$; $F(1, 952) = 11.18$, $p < .001$, $\eta_p^2 = .01$; and $F(1, 952) = 16.90$, $p < .001$, $\eta_p^2 = .02$, respectively.

Results for age indicated that older adolescents were generally less tolerant than younger adolescents. However, further inspection of each separate practice showed that the negative linear effect of age was strongest in case of the schools and nonsignificant in case of the handshaking. For ease of presentation, means are presented for three different age groups in Table 3.

As expected, for education we found that students in the highest level of education were more tolerant of Muslim practices than students in the lowest level (Table 3). However, post hoc analyses showed that for the imam's speech no difference in acceptance existed between the educational levels. Finally, there were differences between boys and girls for all cases, but the direction of the relation between gender and tolerance was not the same for each case (Table 3). Girls were more tolerant than boys with the exception of the imam's speech. For this particular case, boys were significantly more tolerant than girls.

Tolerance of persuasion. The first ANOVA with tolerance of persuading fellow Muslims as the dependent repeated measures variable yielded a significant effect for the type of practice, $F(3, 2898) = 162.32$, $p < .001$, $\eta_p^2 = .16$. Pairwise comparison showed, again, that the least tolerant judgments were given with respect to the imam persuading others ($M = 1.81$, $SD = 0.95$), followed by the female Muslim teacher ($M = 2.08$, $SD = 0.99$), and the students wearing a headscarf ($M = 2.34$, $SD = 1.10$). Unexpectedly, however, the level of tolerance was highest with respect to the Islamic schools ($M = 2.52$, $SD = 1.09$).

The second ANOVA showed that there was a significant main effect of age, $F(1, 960) = 4.33$, $p < .05$, $\eta_p^2 = .004$, and significant interactions between type of practice, and educational level and gender, respectively, $F(6, 2880) = 2.85$, $p < .01$, $\eta_p^2 = .01$, and $F(3, 2880) = 5.65$, $p < .001$, $\eta_p^2 = .01$. Table 4 shows mean levels of tolerance by educational level, gender, and age. Again, and as expected, older participants were less likely to give tolerant judgments. Next, educational level had only an effect for the case of the imam's speech: The higher educated were even less tolerant of the imam trying to persuade other Muslims. Boys and girls differed from each other in their level of tolerance of a Muslim teacher persuading others not to shake hands with men, and in the case of the imam. In the former, girls were found to be more tolerant than boys, in the latter it was the other way around.

Table 3
Mean Scores and Standard Deviations (in Parentheses) for Tolerance of the Four Types of Behavior by Educational Level, Gender, and Age: Study 2

	Headscarf	School	Hand	Speech	Total
Educational level					
Low	2.16 (1.01)	2.12 (1.03)	2.11 (0.98)	2.01 (0.94)	2.10 (0.70)

13–14	2.40 (1.09)	2.53 (1.06)	2.15 (1.04)	1.88 (0.92)	2.24 (0.77)
15	2.37 (1.08)	2.57 (1.09)	2.07 (0.95)	1.78 (0.97)	2.20 (0.80)
16–17	2.26 (1.21)	2.44 (1.10)	2.03 (1.00)	1.79 (0.96)	2.13 (0.81)

Note. Five-point scale (1–5).

Hence, these results are comparable to the previous analysis on the tolerance of the practice itself. It is important to note that, although differences exist for tolerance of the imam's speech between boys and girls, and between students in higher and lower levels of education, all participants tended to have an intolerant attitude toward this type of behavior. The scores lie well below the neutral midpoint (3) of the scale.

Tolerating Practices Versus Tolerating Persuasion

Next, we examined the difference between the two types of tolerance judgments. For tolerance of the practice itself, answer categories ranged from 1 to 4 with no neutral midpoint. In contrast, tolerance of the public expression in order to persuade others had a scale ranging from 1 to 5 with a neutral midpoint. Therefore, we rescaled the items of both types of questions with the following formula: (item − 1)/(number of answer categories − 1). In addition, we examined the frequencies of the answers given in order to draw meaningful conclusions.

We tested the difference in the two types of tolerance judgments by performing for each of the four cases a simple repeated measures ANOVA, with the type of tolerance as the repeated measure. For the case about the school, the two tolerance scores did not significantly differ. However, and as expected, for the other practices the level of tolerance of the public expression was lower than for the practice itself ($ps < .001$). Additional analyses showed that this pattern was consistent across age, educational level, and gender. Furthermore, for all four cases there were clear differences in percentages of tolerant versus intolerant responses. For the wearing of a headscarf, we found that 43% of the participants thought that this should be accepted. However, trying to persuade other Muslims to wear a headscarf was considered acceptable by only 15% (with an additional 26% answering "neutral"). For the other three cases, we obtained similar results. For the founding of Islamic schools, 35% of the participants thought that this should be accepted but only 18% found it acceptable that people try to persuade other Muslims to found Islamic schools (32% answers neutral). Furthermore, 43% thought that the decision of a female teacher not to shake hands with men should be accepted. However, for the persuasion of others, this percentage was only 10% (19% answers neutral). The percentages for the imam's speech were respectively 21% and 6% (neutral: 15%). These percentages indicate that the participants were less tolerant of attempts to persuade other Muslims than of the practices themselves.

In-Group Identification and Multiculturalism

In-group identification and the endorsement of multiculturalism were negatively associated, $r = -.40$, $p < .01$. We examined whether these two measures were associated with tolerance of the Muslims practices and of the campaigning for social support of fellow Muslims. For both types of tolerance judgments, we conducted a 4 (type of practice) × 2 (gender) × 3 (school level) repeated measures ANOVA, with type of practice as repeated measure, and with age, in-group identification, and multiculturalism as covariates.

Tolerance of practices. For tolerance of the Muslim practices, the between-subjects results indicate a significant effect for the continuous variable multiculturalism, $F(1, 950) = 225.20$, $p < .001$, $\eta_p^2 = .19$. As hypothesized, students who more strongly endorsed a multicultural ideology were more tolerant of Muslim practices. This effect was qualified by an interaction with the type of practice $F(3, 2868) = 24.10$, $p < .001$, $\eta_p^2 = .03$. Simple main effects analyses showed that although multiculturalism was significantly associated with tolerance for all practices, the strength of the relationship differed between the practices. As expected, estimates of the effect size indicated that the effect was much weaker for the imam's speech ($\eta_p^2 = .03$) and strongest in the case of the headscarf ($\eta_p^2 = .13$). The cases of the schools ($\eta_p^2 = .10$) and the shaking of hands ($\eta_p^2 = .11$) were in between.

We also examined the extent to which students endorsing high versus low levels of multiculturalism differentiated between the four different practices. That is to say, we compared students with scale scores equal or above the median (2.75) to students scoring below the median. Means and standard deviations for both groups are given in Table 5. Post hoc tests (LSD) showed that participants who scored high on multiculturalism showed the overall differentiation pattern (highest tolerance for headscarf, lowest tolerance for the imam's speech, with tolerance for schools and handshaking in between). Yet, participants scoring low on multiculturalism only differentiated between the case of the headscarf on the one hand, and the school, handshaking, and speech cases on the other hand.

The repeated measures ANOVA did not reveal a main effect for in-group identification or an interaction effect with the type of practice. However,

Table 5

Mean Scores and Standard Deviations (in Parentheses) for Tolerance of Practices and Persuasion by Multiculturalism and Ethnic Identification (Median Splits)

	Headscarf	School	Hand	Speech
Tolerance of practices[a]				
Multiculturalism low	1.96 (0.89)	1.85 (0.93)	1.87 (0.88)	1.88 (0.89)
Multiculturalism high	2.70 (0.93)	2.45 (0.86)	2.52 (0.87)	2.08 (0.80)
Tolerance of persuasion[b]				
Multiculturalism low	2.09 (1.10)	2.26 (1.15)	1.84 (0.95)	1.73 (0.95)
Multiculturalism high	2.59 (1.03)	2.78 (0.96)	2.31 (0.97)	1.89 (0.96)

[a]Four-point scale (1–4). [b]Five-point scale (1–5).

given the considerable association between in-group identification and the endorsement of multiculturalism ($r = -.40$), we also explored the results of an ANOVA without the multiculturalism measure. This analysis yielded the expected main effect for identification, $F(1, 957) = 37.47$, $p < .001$, $\eta_p^2 = .04$, but no significant interaction effect with the type of practice, $p > .05$. Those identifying strongly as Dutch were less tolerant than those with a low level of identification.

Tolerance of persuasion. The same analyses were repeated with tolerance of the persuasion of fellow Muslims as the dependent variable. As expected, there were significant main effects for both multiculturalism, $F(1, 958) = 86.63$, $p < .001$, $\eta_p^2 = .08$, and for ethnic identification, $F(1, 960) = 3.89$, $p < .05$, $\eta_p^2 = .004$. Participants who endorsed multiculturalism relatively strong were more tolerant than those who were less in favor of multiculturalism. Furthermore, those identifying strongly as Dutch made less tolerant judgments compared to those with low levels of in-group identification.

As expected, the association between multiculturalism and tolerance was further qualified by an interaction effect with type of practice, $F(3, 2874) = 10.15$, $p < .001$, $\eta_p^2 = .01$.

Simple main effect analyses showed that the effect of multiculturalism was significantly smaller in the case of the imam's speech. Estimates of the effect size were comparable in the cases of the headscarf ($\eta_p^2 = .06$), schools ($\eta_p^2 = .06$), and shaking hands ($\eta_p^2 = .07$), and especially low with respect to the imam's speech ($\eta_p^2 = .01$). For in-group identification, no interaction with the type of behavior was found, also not when multiculturalism was excluded from the analyses.

Separate post hoc tests (LSD) for students with a weak versus a strong endorsement of multiculturalism (median split; see Table 5) showed that both groups had the same differentiation pattern with the highest tolerance for persuasion in case of the school, followed by the headscarf and the handshaking, and the lowest tolerance for the imam's speech. However, participants who endorsed multiculturalism relatively strongly made clearer differentiations than those who were less in favor of multiculturalism.

General Discussion

This research examined ethnically Dutch adolescents' tolerance of specific practices by Muslim actors. In trying to maximize the relevance and ecological validity of the research, we used realistic and currently debated issues instead of unfamiliar and fictitious scenarios. In culturally diverse societies, controversies and conflicts are typically about concrete practices and actions, and, at least in Europe, predominantly relate to Muslims (Modood & Ahmad, 2007; Zolberg & Long, 1999).

In general, we found that adolescents were rather negative toward Muslim actors and expressed moderate to low levels of tolerance. However, in agreement with social-cognitive domain theory and previous research findings (e.g., Verkuyten & Slooter, 2007, 2008), it turned out that the acceptance of different types of behavior depended on both content and context. Using domain theory (Turiel, 1983), we expected that the tolerance of Muslim practices depends on the domain that the practices predominantly evoke. According to the theory, people make a distinction between the personal, the conventional, and the moral domains but what content-wise is considered to belong to each of these domains is not self-evident, particularly not in relation to the personal and the social-conventional. Therefore, in Study 1 we first examined whether Dutch adolescents make an empirical distinction between the three domains for the different Muslim practices. We presented the participants with four different cases: Muslim students wearing a headscarf, parents founding separate Islamic schools, a female Muslim teacher refusing to shake hands with men, and an imam who publicly calls homosexuals inferior people. The findings of Study 1 indicate that although these cases are multifaceted, they do differ in the salience of the particular domain they evoked, with the first case predominantly involving the personal domain, the second and third triggering more social-conventional concerns, and the fourth raising moral issues. The distinction between the three domains was found independently of age, educational level, and gender.

Study 2 examined two types of tolerance judgments: tolerance of the particular practices and of campaigns for public support of co-Muslims for these practices. In agreement with the domain theory, it turned out that tolerance was highest in the personal domain and lowest in the moral domain, with the social-conventional domain in between. Thus, the participants were found to be most tolerant of Muslim students wearing a headscarf and least tolerant of the imam's speech. The cases of the Islamic school and the refusal to shake hands, both mainly social-conventional matters, fell in between. This difference was found for both types of tolerance: for the actual practices and for Muslims trying to persuade others to engage in the same practices. The one exception was that campaigning for separate Islamic schools was accepted more than trying to persuade other Muslims to wear a headscarf.

There was a clear difference in both types of tolerance. Previous studies have found that people tend to be more tolerant of campaigns for public support for a dissenting belief than of the practice based on that belief (e.g., Verkuyten & Slooter, 2007; Wainryb et al., 1998; Wainryb et al., 2001). Not only is the higher acceptance of the public expression of dissenting beliefs consistent with the idea of free speech, it can be seen as stimulating debate and as causing less direct harm or injustice than the actual act. However, the current findings clearly show that the adolescents were less tolerant of persuading fellow Muslims than of the practice itself. Campaigning for support and persuading others implies mobilizing Muslims, for example, to start wearing a headscarf, to stop shaking hands with people of the opposite sex, and to found more Islamic schools. Politicians and the media tend to present these practices as "backward" and as threatening Dutch identity and culture (see Scroggins, 2005; Vasta, 2007; Verkuyten & Zaremba, 2005). They would undermine the secular and Christian traditions of the Netherlands. Trying to persuade fellow Muslims to act similarly is likely to be seen as contributing to the "Islamization of Dutch society" and therefore leads to lower acceptance compared to the act itself. Perceived threat is considered the most important predictor of intolerance (see Gibson, 2006), but it should be noted that we did not measure feelings of threat. However, in a previous study it was found that these feelings underlie Dutch adolescents' intolerance of Muslims (Van der Noll et al., 2010).

The importance of intergroup factors for understanding tolerance judgments was also found in relation to in-group identification and the endorsement of multiculturalism. Using SIT (Tajfel & Turner, 1979), we predicted that participants identifying strongly as Dutch would be less tolerant. This turned out to be the case for the practice itself (in the analysis without multiculturalism) and for the persuasion of fellow Muslims to act similarly. However, the findings for the endorsement of multiculturalism were stronger than for in-group identification and a similar result has been found in another study on Dutch adolescents' tolerance of Muslims (Van der Noll et al., 2010). One reason is that in-group identification is typically associated with in-group evaluation and not necessarily with the evaluation of out-groups, whereas, in the European context, multiculturalism is predominantly seen as focusing on out-groups (Verkuyten, 2006). In addition, compared to group identification, multicultural ideology is more closely related to questions of how to deal with dissenting beliefs and practices. Thus, multiculturalism seems to provide a general ideological view about the importance of cultural diversity that emphasizes that people should be recognized and valued in their group identity, and that there should be social equality and equal opportunities. This result is in agreement with research that has shown that beliefs about democratic processes and the protection of minority rights is a primary source of political tolerance (McClosky & Brill, 1983; Sullivan & Transue, 1999).

However, these results indicate that adolescents' tolerance judgments of out-group behaviors are driven not only by intergroup factors but also by moral concerns. Participants high on multiculturalism tended to tolerate practices that raise mainly personal and conventional considerations but were less accepting of the practice that was predominantly perceived as a moral transgression. The endorsement of the value of cultural diversity appears not to be unlimited. Multiculturalism does not imply moral relativism in which all practices and ideas are judged equally right and acceptable (Lukes, 2008). Respecting other cultural communities and their practices is difficult when concerns and considerations of others' welfare and fairness are involved. Already at the age of 5, children have been shown to think that some beliefs are relative and others not, and that their judgments of relativism differ from their tolerant judgments of divergent beliefs (Wainryb, Shaw, Langley, Cottam, & Lewis, 2004).

We also examined the development of tolerance by focusing on the effects of age, education, and gender. In contrast to the idea of an age-related progression from less to more principled reasoning and thus a more tolerant attitude (e.g. Enright & Lapsley, 1981; Enright et al., 1984), our results actually show the opposite. Older participants were found to be less tolerant across the range of practices and of both the practice itself and the persuasion of others. These results are in line with findings of a previous study that found among Dutch adolescents a negative association between age and the acceptance of Muslims founding separate schools (Verkuyten & Slooter, 2007). As argued by Killen and Stangor (2001), with age children become increasingly concerned about the nature of social groups and about group norms and expectations (Abrams & Rutland, 2008). It is thus likely that the older participants are more concerned about the functioning of the Dutch society and tend to see the Muslim practices as threatening the norms and values of their in-group. Hence, similar to research that has examined tolerance and children's and adolescents' reasoning about civil liberties (e.g., Helwig, 1995, 1997; Ruck et al., 1998; Wainryb et al., 1998; Wainryb et al., 2001), the current findings do not support a global stage interpretation. Rather, the findings suggest that with age adolescents tend to evaluate concepts of rights and freedoms increasingly in relation to other considerations and concerns, including the intergroup context.

In agreement with previous findings (see Verkuyten & Slooter, 2007; Vogt, 1997), the level of education of the participants was significantly and positively associated with tolerance. However, this effect differed between the types of practices that the participants were asked to evaluate (Wainryb et al., 1998). Educational differences were largest in the case of the headscarf and almost absent in relation to the moral issue of the imam's speech. Compared to participants in the lower levels of education those in the higher levels differentiated more between the different types of practices. Chong (1993) found that in discussing group rights, higher educated students tended to focus on the right itself, whereas the lower educated tended to focus on the group. For our research, this might mean that adolescents in the lowest level of education were predominantly concerned about the outgroup of Muslims whereas the higher educated tended to evaluate the nature of the practices. This interpretation implies that a focus on the actual practices rather than on the group itself does not lead to higher tolerance of persuading fellow Muslims, on the contrary.

Girls were found to be more tolerant than boys in the cases of the headscarf, the school, and the shaking of hands. However, for the imam's speech the picture was reversed, with girls being somewhat less tolerant than boys. It could be argued that females are more likely to reason from a care or welfare perspective (Gilligan, 1982), which makes them more sensitive to the potential (psychological) harm that is inflicted upon homosexuals by the imam's speech. However, systematic research has shown that gender does not explain variability in moral reasoning development (see Walker, 2006). Furthermore, the care perspective does not explain why female adolescents were actually more tolerant than male adolescents in the three other cases that involved freedoms and rights. In two of these three cases, the actors were women and this could have made the female participants' gender identity salient. As a result, their responses might have been influenced by their shared gender identity with the Muslim females in the scenarios. Furthermore, children know that males are considered of higher status than females and the female participants' higher tolerance for these two practices might be a reaction to the lower status and power of women (see Powlishta, 2004). It is also possible that females are more sensitive to issues of rights and freedoms because they have more experiences with gender discrimination and exclusion (e.g., Theimer, Killen, & Stangor, 2001). Future studies could test these different interpretations, for example, by presenting the participants with various practices that were carried out by both male and female Muslims.

Questions on the acceptance of minority practices and minority rights can involve many different situations and issues, and tolerance might also depend on the national context. Islam has moved to the center of debates in most European countries and the retreat of multicultural policies is not restricted to the Netherlands (Joppke, 2004; Zolberg & Long, 1999). Muslims are typically perceived as threatening and they are evaluated rather negatively by majority group populations across Europe (Strabac & Listhaug, 2008). There are strong debates about the acceptance and accommodation of Islamic practices within most liberal states. So, it is likely that our findings apply to other national contexts. Perhaps, the mean level of tolerance for the various practices differs across contexts, but the differentiation between the different domains, as proposed by sociocognitive domain theory, and the role of the endorsement of multiculturalism and in-group identification, as proposed by intergroup approaches, are likely to be similar. Future studies should examine this generality issue more closely and these studies could also examine the judgments of Muslim adolescents (Verkuyten & Slooter, 2008).

In this research, we used questions with precoded answer categories and we did not ask participants to give their reasons for tolerating or not tolerating particular practices. But children and adolescents form judgments on the basis of various concerns and considerations that are evaluated and assessed in relation to each other and the situation to which these apply (Turiel, 2002). That means that there is flexibility of thought and that the same practice can raise very different concerns. For example, the wearing of a headscarf does not only have to be considered a personal choice but can also raise social-conventional concerns and moral issues of gender equality. Similarly, the practice of founding Muslim schools can raise important conventional concerns but typically also involves matters of equal rights. But the fact that different interpretations and justifications are possible does not mean that socially shared or dominant interpretations do not exist. Both of our studies show that, in general and from the perspective of adolescents, some practices more than others raise moral, or conventional, or rather personal concerns. Calling homosexuals inferior people is typically considered harmful and rejected by the great majority of our participants, whereas the wearing of a headscarf is seen more as a personal decision. Thus, we focused on the distinctions made by adolescents themselves and we examined their tolerance judgments in relation to this. However, it would be useful to study adolescents' social reasoning about these topics and to examine the ways in which they weigh and coordinate various considerations in making judgments.

In conclusion, we drew on social-cognitive domain theory and SIT for understanding adolescents' tolerance of practices by Muslims actors, and we demonstrated the fruitful outcome for combining these theoretical frameworks. In studying out-group evaluations and behaviors, an increasing number of studies use an integrated framework by drawing on both developmental and social-psychological theories (see Killen et al., 2006). Previous research, for example, has studied the role of group identity and stereotypic expectations in children's reasoning about peer inclusion and exclusion (e.g., Abrams et al., 2008; Killen & Stangor, 2001). We have tried to make a contribution to this literature by focusing on aspects of tolerance regarding concrete Muslim practices that are, or recently were, debated in the Dutch context. Adolescents were found to make a distinction between practices that they evaluated negatively but regarded mainly a personal matter, practices that predominantly violate conventional norms, and practices that violate moral norms. The level of tolerance differs between these domains and intergroup factors appear to be less important for the acceptance of out-group practices that evoke moral concerns. Our findings indicate the importance of using an integrative social-developmental perspective. By combining cognitive domain theory and SIT, we were able to formulate specific predictions and improve our understanding of adolescents' tolerance of dissenting practices.

This understanding might be of use for developing adequate interventions to improve tolerance, which is foundational for equality and the development of harmonious intergroup relations. Most lines of thinking argue that the reduction of stereotypes and prejudice is necessary for these kinds of relationships to develop. However, our knowledge and ability to reduce stereotypes and prejudice remains limited. Generalized perceptions and negative beliefs and feelings do not appear to be easy to change or to reject. The importance of tolerance is that it keeps these beliefs and feelings from becoming negative actions, thereby forming the first crucial step toward civility or the last barrier to conflict (Vogt, 1997). Tolerance also does not imply relativism in which it is argued that one should refrain from value judgments in assessing other groups (Lukes, 2008). Tolerance always has limits and does not imply a full acceptance and valuing of all social practices of other groups, such as potentially harmful activities, illiberal internal rules, and inequalities. A decision of whether a particular practice should be tolerated always involves a variety of considerations and the results show that adolescents evaluate different practices differently. This means, for example, that effective civics education has to focus on the related questions of what should and what should not be tolerated and why. Furthermore, our findings suggest that an educational emphasis on cultural diversity and multicultural recognition is a promising avenue for improving majority group adolescents' tolerance of Muslims. Participants who endorse multiculturalism more strongly appear to be more tolerant, but much less so when it comes to the imam's harmful speech. Thus, it seems important to stimulate multicultural recognition but without the relativism that is found in some forms of multiculturalism that tend to celebrate diversity unconditionally.

The Development of Core Cognitive Skills in Autism: A 3-Year Prospective Study

Elizabeth Pellicano

Institute of Education, London, and University of Western Australia

This longitudinal study tested the veracity of one candidate multiple-deficits account of autism by assessing 37 children with autism (*M* age = 67.9 months) and 31 typical children (*M* age = 65.2 months) on tasks tapping components of theory of mind (ToM), executive function (EF), and central coherence (CC) at intake and again 3 years later. As a group, children with autism showed poor false-belief attribution, planning ability, and set-shifting, together with enhanced local processing at both time points. At an individual level, however, the profile was far from universal at either intake or follow-up. Moreover, autistic children demonstrated significant changes over time in ToM and EF, but not CC, over the 3-year period. The challenges these findings pose for a multiple-deficits account are discussed.

The past few decades have seen considerable research efforts devoted to isolating a single underlying cognitive deficit that could provide a unifying explanation for the ''triad of impairments'' in autism—the severe difficulties in reciprocal social interaction and communication, and restricted interests and repetitive behaviors (American Psychiatric Association [APA], 1994). Three cognitive theories in particular have dominated the field: (a) the theory-of-mind (ToM) hypothesis, which claimed that autism is caused primarily by a specific inability to impute mental states to oneself and to others (Baron-Cohen, Leslie, & Frith, 1985); (b) the executive dysfunction hypothesis, which proposed that the symptoms of autism are a result of a primary problem in the planning and execution of complex actions (Hughes & Russell, 1993; Ozonoff, Pennington, & Rogers, 1991); and (c) ''weak'' central coherence (CC) theory, which posited that inherent to autism is an unusual tendency to focus on individual, local elements rather than global wholes (Frith, 1989; Happé & Frith, 2006).

The notion of a single cause at the cognitive level of analysis has, however, been challenged on two main grounds. First, all three influential ''single-deficit'' models have struggled to satisfy key criteria for an explanatory account of autism, namely, that the putative deficit should be ''universal, specific, and necessary and sufficient to cause the symptoms of the disorder'' (Pennington & Ozonoff, 1996, p. 57), and show persistence or stability over time (Ozonoff & McEvoy, 1994; Rutter, 1983; see Rajendran & Mitchell, 2007, for a review). Second, recent research has called into question the very premise underpinning the search for a core cognitive deficit: that the behaviors central to autism cluster together more often that what would be expected by chance as a result of shared etiology (Happé & Ronald, 2008; Happé, Ronald, & Plomin, 2006; Mandy & Skuse, 2008). Investigations of the broader autism phenotype have demonstrated that among those relatives of individuals with autism who display subclinical autistic features, the majority of these family members show behaviors in isolated symptom domains (e.g., social difficulties in the absence of repetitive behaviors, etc.) rather than a combination of these symptoms, albeit in more subtle form than in autism itself (e.g., Bolton et al., 1994). Furthermore, recent findings from a population-based study investigating autism-related traits in over three thousand 7- to 9-year-old typically developing twin pairs found that the cross-trait genetic correlations were surprisingly modest to low both across the general population and in children lying at the extreme end of the distributions, suggesting that largely independent genes may be

operating on each aspect of the triad of impairments in autism (Ronald et al., 2006). Also, a considerable number of children in this study displayed behavioral difficulties in isolation (e.g., social difficulties only, communication problems alone). Both sets of findings provocatively suggest that the triad of impairments may in fact be dissociable, raising the possibility of distinct causes for each aspect of the behavioral phenotype.

In light of these challenges, Happé and colleagues have argued that ''at the cognitive level, as at the symptom/behavioral and genetic levels, autism may be characterized by fractionable impairments'' (Happé & Ronald, 2008, p. 296). Consequently, they have called for researchers to ''abandon the attempt to find a single cognitive explanation'' (Happé, Ronald, et al., 2006, p. 1219) in favor of an explanation encompassing coexisting atypicalities in *multiple* cognitive domains. These authors offered one candidate account in which a combination of cognitive atypicalities in three core domains—ToM, executive function (EF), and CC—exists in autism, where each atypicality underpins a distinct aspect of the behavioral phenotype. Since these atypicalities are held to be largely *independent* of each other at the phenotypic and genetic levels, autistic symptoms are therefore viewed as the result of multiple, *primary* cognitive atypicalities.

Recent evidence supports this view. Pellicano, Maybery, Durkin, and Maley (2006) found that young children with an autism spectrum disorder (ASD; $n = 40$) as a group did in fact demonstrate the cognitive profile proposed by Happé and colleagues, including difficulties in aspects of ToM (false-belief understanding) and EF (planning, cognitive flexibility) accompanied by weak CC (enhanced local information processing), relative to age- and ability-matched typical children. This support at the group level was somewhat tempered, however, by a failure to demonstrate the presence of this specific cognitive profile in each child with ASD.

One crucial question is how this specific cognitive profile manifests itself over time. Autism is generally understood as a pervasive, lifelong condition (APA, 1994), and therefore any putative explanation of the pathogenesis of autism should be able to account for the continuities and discontinuities that take place across the life span. Despite the wealth of research on specific cognitive skills in autism, however, there have been disappointingly few empirical studies tracking the *development* of such skills in autism—even within a single-deficit framework. The overarching goal of the current study therefore was to investigate longitudinally the multiple-deficits account proposed by Happé, Ronald, et al. (2006) focusing specifically on questions regarding developmental persistence—both at the group level and at the individual level.

Before describing this study it is worth considering briefly the findings of the five existing longitudinal studies. Remarkably, only four longitudinal investigations have traced developmental changes in ToM. Holroyd and Baron-Cohen (1993) followed 17 of 20 children with autism described originally in Baron-Cohen et al. (1985) and reassessed their false-belief understanding 7 years later. No overall gains in participants' ToM skills were found: Only 3 children passed the simple ''Sally–Ann'' test at follow-up (including 2 of 4 children who had succeeded on this task 7 years earlier), and no child passed a more advanced ToM test. Ozonoff and McEvoy (1994, Experiment 2) also reported no significant changes in the proportion of cognitively able autistic adolescents passing simple and more advanced ToM tasks over a 3-year period. Indeed, the scores of only 4 adolescents with autism improved over time. The authors therefore concluded that, overall, ToM abilities progress little with development.

Two recent studies, however, paint a more positive picture. Steele, Joseph, and Tager-Flusberg (2003) found significant improvements in autistic children's ToM skills over a 1-year period, with initial vocabulary level, rather than chronological age, predicting a significant (yet small; 3%) proportion of the variance in later ToM scores. Such gains, however, were driven largely by improvements on tasks tapping early-emerging ToM skills (understanding of pretense and desire) rather than on tasks of false-belief understanding. Serra, Loth, van Geert, Hurkens, and Minderaa (2002) also reported significant gains in a range of ToM skills over a 6-month period in preschool children with a mild variant of autism (pervasive developmental disorder–not otherwise specified; PDD–NOS), even though children with PDD–NOS developed at a slower rate than younger typically developing children. Their analysis, however, examined changes over time for an omnibus ToM score rather than for individual ToM task scores rendering it unclear whether such gains occurred for false-belief understanding per se.

To date, only two studies have investigated the developmental course of EF. In Ozonoff and McEvoy's (1994, Experiment 1) 3-year follow-up study, nonautistic adolescents with learning disability showed significant gains in planning efficiency (on the Tower of Hanoi) and made fewer perseverative responses (on the Wisconsin Card Sort Test [WCST]), but concomitant improvements were not evident in adolescents with autism. They concluded that, akin to their findings on ToM, difficulties in EF also persist over time. Griffith, Pennington, Wehner, and Rogers (1999) reported similar findings in preschoolers with autism on a spatial reversal task, a test of cognitive flexibility. Despite there being a trend for children with developmental delay to commit fewer perseverative errors at follow-up, autistic children's performance did not change significantly within the space of 1 year.

The findings from these longitudinal studies indicate that there are, on the whole, few changes in ToM or EF over time, implying that there might be a ceiling on the extent to which such abilities can develop in people with autism. Yet, there is wide variability in the age and ability of participants tested within and across the five studies, which not only makes comparisons between these few studies difficult, but also can potentially swamp longitudinal effects (i.e., improvements) within studies. Also, with the exception of Ozonoff and McEvoy's (1994) study, there has been no investigation of developmental changes in *multiple* cognitive domains; it is unclear, therefore, whether all core aspects of the cognitive phenotype (cf. Happé, Ronald, et al., 2006) take a similar developmental course. Indeed, no study has examined longitudinally local information processing in autism. The progression of CC therefore remains unknown.

The limited knowledge on the developmental course of each of the three cognitive domains presents an initial difficulty for a multiple-deficits account of autism. A complete picture of the development of the condition requires an understanding of the potential changes that take place over time within each domain, in addition to knowledge of the factors that influence such changes. This longitudinal study sought to take a crucial step in this direction. To this end, Pellicano et al.'s (2006) samples of cognitively able children with ASD and typically developing children were followed prospectively and reevaluated 3 years later on similar measures tapping key components of ToM, EF, and CC.

The primary aims of this study were twofold. The first aim was to test whether Happé, Ronald, et al.'s (2006) specific cognitive profile persisted across time both at the group level and at the individual level. If the putative cognitive profile—atypicalities in ToM, EF, and CC—is indeed central to autism, then the group of children with autism should show atypicalities in all three domains relative to a group of typically developing children both at intake and at follow-up (cf. Ozonoff & McEvoy, 1994). Furthermore, if the specific combination of atypicalities in ToM, EF, and CC underlies autistic symptoms as Happé et al. proposed, then this profile should be present in all, or almost all, autistic children at both time points.

The second aim of this study was to determine the nature and extent of developmental changes in ToM, EF, and CC, and to identify potential predictors of cognitive change. The majority of existing studies has failed to demonstrate developmental improvements in false-belief understanding and aspects of EF. It was expected, however, that longitudinal changes might be more readily detected in a sample of children with autism who were selected initially to be of at least average intellectual functioning and who fell within a restricted age range. Furthermore, language has been implicated in theoretical models of the development of both ToM (e.g., de Villiers, 2000) and EF (e.g., Russell, 1996), and has been linked empirically to autistic children's skills in ToM (e.g., Happé, 1995), EF (e.g., Liss et al., 2001; Pellicano, 2007), and CC (e.g., Pellicano et al., 2006). It was hypothesized, therefore, that for children with autism, individual differences in general cognitive ability, particularly verbal ability, would be influential in predicting developmental change in all three cognitive domains.

Method

Participants

A total of 90 children participated in the initial study (Time 1): 45 children with an ASD (40 boys) and 45 typically developing children (37 boys). Briefly, all children in the ASD group had received an independent clinical diagnosis of either autism ($n = 31$), PDD–NOS ($n = 12$), or Asperger syndrome ($n = 2$), according to *DSM–IV* criteria (APA, 1994) and met either full or partial criteria on the Autism Diagnostic Interview–Revised (ADI–R; Lord, Rutter, & Le Couteur, 1994; see Pellicano et al., 2006, for details). At intake, the ASD group had a mean age of 67.2 months ($SD = 10.51$, range = 49–88) and the typically developing group had a mean age of 65.1 months ($SD = 11.80$, range = 48–88). No child had a coexisting medical or developmental condition as reported by parents, or obtained a verbal or nonverbal IQ score below 80, as assessed by the Peabody Picture Vocabulary Test–Third Edition

(PPVT–III; Dunn & Dunn, 1997) and the Leiter International Performance Scale–Revised (Leiter–R; Roid & Miller, 1997), respectively. Note that unlike more standard IQ tests, which assess both receptive and expressive language ability, the measure used here to index verbal IQ assessed children's receptive vocabulary skills alone. Children with autism were recruited through community contacts in southwest Western Australia. The majority of children were White, and the parents were of mixed socioeconomic backgrounds, although specific data on socioeconomic status and educational attainment levels were not recorded.

Attempts were made to contact all families approximately 3 years after their involvement in the initial study to invite them to participate in the follow-up study (Time 2). Sixty-eight families were retraced and gave consent for reassessment (76% of the original sample; see Table 1). The mean time between the initial and follow-up studies was 32.9 months for the ASD group and 32.7 months for the typical group. Thirty-seven of 45 children with ASD (82%) were available for further testing. Of the 8 families who were unavailable for reassessment, 2 had relocated to a different state, while 6 families had moved and were untraceable. The 37 children with autism (33 boys) in the follow-up group were not significantly different from those who were not reassessed (*n* = 8) in terms of chronological age, *F*(1, 44) = 0.28, *p* = .60; verbal ability, *F*(1, 44) = 0.63, *p* = .43; nonverbal ability, *F*(1, 44) = 1.27, *p* = .27; or total algorithm score on the ADI–R, *F*(1, 44) = 1.90, *p* = .18. The follow-up group consisted of 26 children with autism, 9 children with PDD-NOS, and 2 children with Asperger syndrome, all of whom met full or partial criteria on the ADI–R conducted at Time 1 (social domain: *M* = 17.81, *SD* = 5.74; communication domain: *M* = 13.22, *SD* = 4.37; repetitive behaviors domain: *M* = 6.68, *SD* = 2.42). The Autism Diagnostic Observation Schedule–Generic (ADOS–G; Lord, Rutter, DiLavore, & Risi, 1999) was administered at follow-up to index these children's current sociocommunicative symptoms (Social Interaction score: *M* = 8.54, *SD* = 3.51; Communication score: *M* = 4.11, *SD* = 2.22; Total algorithm score: *M* = 12.62, *SD* = 4.98).

Table 1
Descriptive Statistics for Chronological Age, Verbal Ability, and Nonverbal Ability for the Autism Spectrum Disorder (ASD; n *= 37) and Typically Developing (*n *= 31) Groups at Both Time Points*

	ASD	Typical		
Variable	*M* (*SD*) Range	*M* (*SD*) Range	*F*	*p* value
Chronological age				
Time 1	67.92 (10.42) 49–88	65.19 (12.64) 48–88	0.95	.33
Time 2	100.84 (11.15) 80–123	97.94 (13.48) 75–122	0.94	.34
Verbal IQ (PPVT–III)				
Time 1	97.08 (11.52) 80–122	100.97 (8.72) 87–120	2.38	.13
Time 2	93.89 (17.88) 62–138	99.64 (10.53) 80–123	2.48	.12
Nonverbal IQ (Leiter–R)				
Time 1	113.27 (13.93) 83–141	115.61 (16.42) 89–147	0.40	.53
Time 2	104.35 (12.72) 80–135	106.97 (10.16) 93–129	0.85	.36

Note. PPVT–III = Peabody Picture Vocabulary Test–Third Edition; Leiter–R = Leiter International Performance Scale–Revised.

Of the initial sample of 45 typical children who were recruited from several local mainstream preschools and primary schools, 31 (69%) took part in the follow-up study (see Table 1). One family had relocated, 4 families declined to participate, and 10 families were untraceable. The 31 typical children (25 boys; 81%) involved in the follow-up study did not differ significantly from the 14 children who did not participate in terms of age, *F*(1, 44) = 0.02, *p* = .87; verbal ability, *F*(1, 44) = 1.66, *p* = .20; or nonverbal ability, *F*(1, 44) = 1.78, *p* = .19, at intake. Parents of typically developing children completed the Social Communication Questionnaire (Rutter, Bailey, & Lord, 2003) to ensure that no child in this group displayed clinically significant levels of autistic symptomatology; all scores were well below the cutoff score of 15 for autism at Time 1 (*M* = 4.00, *SD* = 3.32) and Time 2 (*M* = 3.50, *SD* = 2.85).

Measures

Children completed a variety of measures assessing key aspects of cognition at each time point.

Verbal and nonverbal ability. At both time points, the PPVT–III (Dunn & Dunn, 1997) was used to assess children's receptive vocabulary and four subtests of the Leiter–R (Roid & Miller, 1997) were used to index nonverbal ability: *Matching* (a match-to-sample task using pictures of objects and abstract patterns), *Associated Pairs* (an associative memory task in which children were required to establish associations between pairs of pictured objects), *Forward Memory* (a visual short-term memory task that involved children copying the examiner's pointing sequence), and *Attention Sustained* (a visual attention task, which entailed identifying multiple target stimuli among distractor stimuli). Standard scores are reported in Table 1, but raw scores are used in correlational and regression analyses since such scores have not been adjusted for age, and therefore are more sensitive to developmental change.

Theory of mind. At each time point, children were presented with three standard false-belief prediction tasks to index ToM ability. For the *first-order unexpected-contents task* (based on Perner, Leekam, & Wimmer, 1987), children were shown three different boxes (e.g., milk carton) containing unexpected contents (e.g., rubber bands). After the lid of each box was replaced, they were asked to recall their own false belief (e.g., "Before you looked inside, what did you think was in the box?") and to predict another's false belief (e.g., "If I show this box to Mum, what will she think is inside?"). Children also answered a control question (e.g., "What is in the box really?") following each false-belief question. For the *first-order unexpected-transfer task* (based on Baron-Cohen et al., 1985), children were shown six different scenarios in which one character either displaced or substituted another character's object. At the end of each trial, children were asked a critical belief question (e.g., "Where will Sarah look for her apple?") and two control questions (e.g., "What is really in the bag?" and "What was in the bag in the beginning?"). For the *second-order unexpected-transfer task* (based on Perner & Wimmer, 1985), children were shown two displacement scenarios similar to those in the first-order unexpected-transfer task, although this time they witnessed the protagonist watching the transfer through a window. For each trial, they were asked to attribute a mistaken belief about a belief to a character (e.g., "Where will Tom think that Jane will look for her book?") as well as reality (e.g., "Where is the book really?") and memory (e.g., "Where did Jane put the book in the beginning?") control questions.

Children were given a score of 1 for each correctly answered false-belief test question. At both time points, children were asked 14 test questions: 6 points from the first-order unexpected-contents task (3 for recalling their own belief and 3 for recalling another's false belief), 6 points from the first-order unexpected-transfer task, and 2 points from the second-order unexpected-transfer task. All children correctly answered control questions, with the exception of 1 child with autism who failed the control questions on one second-order trial at Time 2. To avoid loss of data, this child was given a score of 0 of 2 on this task only.

Executive function. At both time points, children completed two measures each tapping a key component of EF, including planning ability and cognitive flexibility. Both EF components have been identified consistently as being disrupted specifically in autism (see Hill, 2004). The *Tower of London task* (Shallice, 1982; see also Hughes, 1998b) assessed children's higher order planning ability. Children were presented with three colored beads (red, white, black) arranged in a particular configuration (start state) on a wooden tower structure consisting of three vertical pegs of increasing size (small, medium, and big). They were then shown a picture of the beads in a different configuration (goal state) and asked to move the beads on their apparatus one at a time to match the goal state within the least possible number of moves (this number was clearly stated on the picture). After three practice trials, children were given problem sets of increasing difficulty (four trials of 1-, 2-, 3-, and 4-move problems). At Time 2, an additional 5-move problem set was included to increase task difficulty and extend the range of possible scores. Testing ceased if children failed all four trials within a problem set. The number of moves taken and rule violations were recorded. Children were given a score of 1 for each trial if they reached the goal state within the minimum number of moves and without violating any rules (Time 1: maximum score = 16; Time 2: maximum score = 20). High scores indicate good planning ability.

Cognitive flexibility was assessed using two developmentally sensitive card-sorting tasks. Both tasks were similar in nature to the traditional WCST (Heaton, 1981) and assessed the ability to switch flexibly between sorting categories in response to feedback. At Time 1, Hughes's (1998a) *teddy-bear set-shifting task* was used. There were three decks of cards, which differed in terms of either color (green vs. pink, blue vs. red, or yellow vs. purple), picture shown (hearts vs. diamonds, squares vs. moons, or stars vs. happy faces), and size of picture (small vs. large). To begin, children were presented with a teddy bear and one deck of cards, and were told that they were to work out which cards teddy liked best. If the card was one of teddy's favorites, the child posted it into a postbox. Alternatively, if the card was not one of teddy's favorites, then the child turned the card facedown on the table. Feedback was provided after each trial. When the child had successfully sorted six cards consecutively, or when a maximum of 20 trials had been presented, the sorting rule (e.g., color, shape, size) changed, upon which he or she was presented with a new teddy bear and new deck of cards. Following Hughes, children were not alerted to a change in sorting rule; this was implicit in the fact that children were presented with a new situation. Set-shifting performance was rated by the proportion of errors committed following the first sort to criterion.

At Time 2, children were administered a more difficult *computerized set-shifting task* (Comerford, 2005). Children were told that they would see one (target) card that appeared at the top of the screen, and that they would be required to match this card with one of four (response) cards presented at the bottom of the screen. There were 24 response cards, which varied on three dimensions (color, form, and background); all cards shared only one attribute with three of the four response cards and no attribute with the fourth card. Each card therefore could be sorted according to three rules (color, form, or background). Feedback was provided for each trial: The words *correct* or *incorrect* would appear in center screen. After the child had sorted six consecutive cards correctly, the rule changed (e.g., from color to form) without warning. Testing continued until the set of 24 cards had been presented twice (48 trials in total). To ensure compatibility with the earlier set-shifting task, the main variable of interest was the proportion of errors committed following the first sort to criterion. For both set-shifting tasks, a low score (i.e., minimal errors) indicates good cognitive flexibility.

Central coherence. Two visuospatial tasks were used to assess children's local processing bias: the *Children's Embedded Figures Test* (CEFT; Witkin, Oltman, Raskin, & Karp, 1971) and the *Pattern Construction task* from the Differential Ability Scales (Elliott, 1990). In the CEFT, children initially were shown a target shape (a triangle) and asked to find this shape hidden in a number of larger meaningful figures as quickly as possible (total 11 trials). There was a single target shape per figure, and children scored 1 point for each correctly identified target (maximum score = 11). The time taken to find the target also was recorded and was the dependent variable of interest. If children were unable to locate the target within 30 s, the maximum time (30 s) was given on that trial. Faster times are indicative of weak CC (i.e., better local processing).

In the Pattern Construction task, which is similar in nature to Wechsler's (1999) Block Design subtest, children were asked to produce a number of increasingly complex patterns using three-dimensional blocks to match a two-dimensional design, as quickly as possible. Similar to the standard Block Design subtest, individual items were scored from a minimum of 0 points (failure) to a maximum (which varied across items), based on accurate reproduction and extra points for speed. Item scores were summed and then converted to ability scores using tables in the manual (Elliott, 1990), which takes into account the child's raw score and the difficulty of the items administered. Higher scores are indicative of better performance (i.e., weak CC).

Individuals with autism have been shown to outperform comparison individuals on both tasks, and their superior performance has been attributed to an enhanced ability to presegment the design into its constituent parts, which enables them to locate rapidly either the hidden figure (in the case of the CEFT) or the appropriate blocks from which to reconstruct the pattern (in the case of the Pattern Construction task; see Happé & Frith, 2006, for a review).

General Procedure

Ethical approval for this study was granted by the University of Western Australia's Human Research Ethics Committee, and informed written consent was obtained from parents of all children prior to participation. At each time point, children were seen individually on two occasions, each lasting approximately 1–1.5 hr, either at the family home or at the university. Tests of verbal and nonverbal ability were always administered first followed by tests of specific cognitive skills, the order of which was randomized across participants.

Results

The first section presents preliminary descriptions of data screening and analyses on group matching variables. The subsequent sections present the main results for each cognitive domain separately, including descriptive statistics for the individual tasks and results of analyses assessing developmental persistence and developmental change—two of the primary goals of this study. Where possible, repeated measures analyses of variance (ANOVAs) on individual task scores, with "group" (ASD, typical) as the between-participants factor and "time" as the within-participants factor, were used to examine between-group differences and within-group change. The results of hierarchical regression analyses on the ASD data specifically are also reported to identify potential predictors of change in specific cognitive skills. Aggregate scores for each cognitive domain were used as dependent variables. Also, to minimize the number of predictors in these analyses, only those early developmental variables (age, verbal ability, and nonverbal ability) that were significantly correlated with the dependent variable were entered as potential predictors. The final section reports the results of analyses to determine whether the putative cognitive profile is characteristic of *individual* children with autism.

Preliminary Data Screening

To begin, scores on the set-shifting tasks and the CEFT were reversed so that high scores reflected good performance. Subsequent data screening revealed that the distributions of cognitive variables met assumptions of normality, with the exception of scores on individual ToM tasks, which were significantly positively skewed for children with ASD. Transformations were applied to these ToM variables to try to normalize the data without success. Given the robustness of ANOVA against violations of normality, group differences on individual ToM tasks were analyzed using parametric tests. Also, and not unexpectedly, typical children performed at ceiling on all false-belief tests at Time 2. Analyses concerning developmental changes in ToM skills therefore were restricted to the ASD group. Data screening for outliers (± 3.5 *SD* of the total sample mean) identified one extreme score on the Pattern Construction task at Time 2 (a child with autism). This score was trimmed by replacing it with the value representing 3.5 *SD* above the overall mean (cf. Wilcox, 2002), and subsequent analyses were conducted using the trimmed score (Table 2 displays the untrimmed scores).

Estimates of reliability were ascertained where possible. For ToM, internal consistency across all 14 trials of the false-belief tasks was high for both children with ASD (Time 1: Cronbach's $\alpha = .87$; Time 2: $\alpha = .94$) and typical children (Time 1: $\alpha = .88$). Cronbach's α could not be calculated for typical children's Time 2 ToM scores since performance was at ceiling for this group. The CEFT (response time) showed modest reliability at both time points in the autism (Time 1: $\alpha = .50$; Time 2: $\alpha = .51$) and typical (Time 1: $\alpha = .51$; Time 2: $\alpha = .47$) groups. It was not feasible to calculate reliability estimates for the Pattern Construction task and EF tasks, as most of these measures incorporate stopping rules as part of their administration. High reliability has been reported previously for the Pattern Construction task in preschool and school-aged children (α ranges between .82 and .90; Elliott, 1990), and for set-shifting tasks in autism (Ozonoff, 1995). For each group, there were significant intercorrelations between individual task scores within each cognitive domain at Time 1 (ToM: $r_{\text{mean}} = .66$; EF: $r_{\text{mean}} = .45$; CC: $r_{\text{mean}} = .42$, all $ps < .05$) and at Time 2 (ToM: $r_{\text{mean}} = .55$; EF: $r_{\text{mean}} = .63$; CC: $r_{\text{mean}} = .45$, all $ps < .05$), indicating good convergent validity. Most of these correlations remained significant when the effects of verbal and nonverbal ability were partialled out (all r_{mean}s > .31).

Group Matching

Descriptive statistics for all matching variables are provided in Table 1. There were no significant differences between the ASD and typical groups in terms of chronological age, verbal IQ, or nonverbal IQ at either time point (all $ps > .12$).

Theory of Mind

Table 2 shows mean scores for individual tasks at each time point. As expected, at Time 1, children with ASD obtained significantly lower scores compared with typical children on the first-order unexpected-contents, $F(1, 67) = 47.70$, $p < .001$, $\eta_p^2 = .42$, and unexpected-transfer, $F(1, 67) = 9.84$, $p < .005$, $\eta_p^2 = .13$, tasks, and the second-order unexpected-transfer task, $F(1, 67) = 12.06$, $p < .001$, $\eta_p^2 = .15$. This pattern of group differences was also evident at Time 2: Autistic children performed significantly worse on both first-order false-belief tasks, unexpected-contents: $F(1, 67) = 7.02$, $p < .01$, $\eta_p^2 = .10$; unexpected-transfer: $F(1, 67) = 31.23$, $p < .001$, $\eta_p^2 = .32$, and on the second-order task, $F(1, 67) = 33.33$, $p < .001$, $\eta_p^2 = .34$, than typical children.

Robust aggregate ToM scores for each time point were computed by averaging children's scores from the three individual tasks (see Table 2). A repeated measures ANOVA on aggregate scores showed main effects of group, $F(1, 66) = 42.08$, $p < .001$, $\eta_p^2 = .39$, confirming the results on individual task scores. There was also a significant main effect of time, $F(1, 66) = 108.40$, $p < .001$, $\eta_p^2 = .62$, indicating a significant *improvement* in ToM scores over the 3-year period across groups. The interaction between time and group was not significant, $F < 1$,

Table 2

Mean Scores for Tasks Tapping Each Cognitive Domain in the Autism Spectrum Disorder (ASD; $n = 37$*) and Typically Developing (*$n = 31$*) Groups at Intake and Follow-Up*

	Group

[a]$n = 36$. [b]Different tasks tapping cognitive flexibility were performed at each time point (see text for details). CEFT = Children's Embedded Figures Test.

although this is most likely due to the ceiling effect present in the typical data. To ensure that the way in which the reported aggregate score was computed did not mask possible deficits on the more difficult second-order ToM tasks, two alternative ToM aggregate scores were constructed. One aggregate score was created by standardizing the scores from each of the three ToM tasks and then deriving the average, and a second score was created by averaging the standard scores of the second-order task and the mean of the two first-order tasks. Subsequent analyses were carried out using these alternative ToM aggregate scores, yet the overall pattern of results remained unchanged.

To examine developmental change within individual children with ASD, the number of children passing and failing each ToM task at Time 1 and Time 2 is presented in Table 3. Success was defined conservatively as ≥ 5 of 6 trials correct (≥ 83%) for each first-order task, and 2 of 2 trials correct (100%) for the second-order task. McNemar's tests showed a significant increase over time in the number of children with ASD passing the first-order

Table 3

Numbers of Children With Autism Spectrum Disorder ($n = 37$*) Passing and Failing Individual Theory-of-Mind Tasks at Intake (Time 1) and Follow-Up (Time 2)*

	Time 2	
Time 1	Fail	Pass
First-order unexpected contents		
Fail: ≤ 4 points	8	23
Pass: 5 or 6 points	0	6
First-order unexpected transfer		
Fail: ≤ 4 points	19	15
Pass: 5 or 6 points	0	3
Second-order unexpected transfer		
Fail: ≤ 1 point	21	16
Pass: 2 points	0	0

unexpected-contents task (16% at Time 1 and 78% at Time 2, $p < .001$), the first-order unexpected-transfer task (8% at Time 1 and 49% at Time 2), and the second-order unexpected-transfer task (0% at Time 1 and 43% at Time 2), all $ps < .001$. All children who passed the first-order ToM tasks at Time 1 also passed these same tasks at Time 2. Of the 9 children who passed either first-order false-belief task at Time 1, all passed the second-order task at Time 2.

A regression analysis using aggregate ToM scores was performed to determine the early predictors of later ToM skills in the ASD group. Time 1 aggregate ToM scores significantly predicted aggregate scores at Time 2 ($\beta = .48$, $R^2 = .23$), $F(1, 36) = 10.57$, $p = .003$. Early verbal ability, $r(35) = .46$, $p < .005$, but not nonverbal ability or chronological age (both $ps > .11$), was significantly associated with later ToM skills. Early receptive-language scores therefore were entered into the model at the second step to determine the additional influence, if any, of this variable on children's later ToM scores. In line with Steele et al. (2003), Time 1 verbal ability explained variance in Time 2 ToM scores over and above Time 1 ToM ($\beta = .30$, $\Delta R^2 = .08$), $\Delta F(1, 34) = 3.88$, $p < .05$, with better vocabulary skills early on predictive of more advanced ToM skills 3 years later. Early ToM scores remained significantly predictive of change in children's ToM scores once variation in early verbal ability had been adjusted for ($\beta = .36$, $p < .05$).

Executive Function

Children's performance on the Tower of London and set-shifting tasks is shown in Table 2. For children's Tower of London scores, a repeated measures ANOVA revealed a significant main effect of group, $F(1, 65) = 37.06$, $p < .001$, $\eta_p^2 = .36$, and time, $F(1, 65) = 125.94$, $p < .001$, $\eta_p^2 = .66$, and a significant Group × Time interaction, $F(1, 65) = 4.69$, $p < .05$, $\eta_p^2 = .07$. Planned comparisons showed that children with ASD obtained significantly lower planning scores than typical children both at Time 1, $F(1, 67) = 40.48$, $p < .001$, $\eta_p^2 = .38$, and at Time 2, $F(1, 67) = 14.55$, $p < .001$, $\eta_p^2 = .18$. Analyses further revealed that children's scores improved significantly over time in both groups, ASD: $t(35) = 10.80$, $p < .001$; typical: $t(30) = 5.64$, $p < .001$. The source of the interaction lay instead with the *extent* of improvements over the 3-year period. Children with ASD made significantly *more* gains in higher order planning (M gain = 5.06, SD = 2.81) than typical children (M = 3.42, SD = 3.37), $F(1, 67) = 4.69$, $p < .05$, $\eta_p^2 = .07$.

How many children showed developmental improvements on the Tower of London task? This question was tackled by determining how many children with ASD showed improvement above and beyond what would be expected given their age and ability. The typical group made an average gain of 3.4 points on the Tower of London task during the 3-year period. The majority of children in the ASD group ($n = 26$; 70% of sample) exceeded this level of improvement (average gain of 5.0 points), compared to 12 typical children (39%).

Separate one-way ANOVAs were carried out on children's set-shifting performance given the use of different tasks at different time points. Children with ASD performed significantly worse than typically developing children on the teddy bear set-shifting task used at Time 1, $F(1, 67) = 18.14$, $p < .001$, $\eta_p^2 = .22$, and on the computerized set-shifting task administered at Time 2, $F(1, 67) = 11.60$, $p < .001$, $\eta_p^2 = .15$, suggesting persistent difficulties with cognitive flexibility.

The significant intercorrelations between Tower of London and set-shifting task scores meant that an EF aggregate score could be computed at each time point by averaging the standard scores for these tasks. Multiple regression analyses demonstrated that individual differences in early EF aggregate scores strongly predicted ASD children's EF performance at follow-up ($\beta = .70$, $R^2 = .49$), $F(1, 35) = 33.22$, $p < .001$. Cross-time correlations revealed that all developmental variables at Time 1 significantly correlated with EF aggregate scores at Time 2, age: $r(35) = .30$, $p < .05$; verbal ability: $r(35) = .48$, $p < .005$; nonverbal ability: $r(35) = .52$, $p < .001$, and therefore all were entered into the model at Step 2. Time 1 EF aggregate scores continued to be significant in this model ($\beta = .66$, $p < .005$), but none of the remaining predictors, however, contributed any unique variance to change in children's EF skills (all $ps > .42$).

Central Coherence

Table 2 shows children's CEFT and Pattern Construction scores. An ANOVA on children's CEFT times revealed significant main effects of group, $F(1, 66) = 124.02$, $p < .001$, $\eta_p^2 = .65$; time, $F(1, 66) = 36.09$, $p < .001$, $\eta_p^2 = .35$; and a significant interaction between group and time, $F(1, 66) = 44.84$, $p < .001$, $\eta_p^2 = .40$. As expected, children with ASD showed a significant advantage on this task, with faster times than typically developing children both at Time 1, $F(1, 67) = 168.29$, $p < .001$, $\eta_p^2 = .72$, and at Time 2, $F(1, 67) = 10.34$, $p < .002$, $\eta_p^2 = .14$. For typical children, the time taken to find the hidden figure reduced significantly over the 3-year period, $t(30) = 7.49$, $p < .001$. Yet this was not the case for children with ASD, whose times remained unchanged, $t < 1$. Comparable results were obtained when median times were used.

An ANOVA on children's Pattern Construction scores revealed main effects of group, $F(1, 66) = 20.75$, $p < .001$, $\eta_p^2 = .24$; time, $F(1, 66) = 60.52$, $p < .001$, $\eta_p^2 = .48$; and a significant Group × Time interaction, $F(1, 66) = 30.87$, $p < .001$, $\eta_p^2 = .32$. Planned comparisons showed that children with ASD performed significantly better than comparison children at Time 1, $F(1, 67) = 50.11$, $p < .001$, $\eta_p^2 = .43$, but failed to maintain their advantage on this task at Time 2, $F(1, 67) = 1.45$, $p = .23$, $\eta_p^2 = .02$. Further within-group analyses showed that, similar to the pattern of results obtained for the CEFT, typical children's scores improved significantly over time, $F(1, 30) = 118.68$, $p < .001$, $\eta^2 = .80$, but ASD children's scores did not, $F(1, 36) = 2.15$, $p = .15$, $\eta^2 = .06$. Examination of individual children's performance over time was addressed in the same way as it had been for children's Tower of London performance. While the ASD group improved, on average, only 4.8 points on the Pattern Construction task between intake and follow-up, typically developing children improved, on average, 25.8 points. Twelve typical children (39%) demonstrated this level of improvement compared with no child in the ASD group.

Central coherence aggregate scores for each time point were created by standardizing the CEFT time and Pattern Construction scores and averaging them. Regression analyses showed that early CC aggregate scores were predictive of change in ASD children's scores over the 3-year period ($\beta = .56$, $R^2 = .31$), $F(1, 35) = 15.85$, $p < .001$. Since Time 2 CC aggregate scores were significantly correlated with initial verbal ability, $r(35) = .64$, $p < .001$, and nonverbal ability, $r(35) = .67$, $p < .001$, but not with age ($p = .10$), the former two Time 1 variables were added to the model at the second step. Nonverbal ability alone contributed an additional 19% of the variance in later CC aggregate scores ($\beta = .50$, $\Delta R^2 = .19$), $\Delta F(1, 34) = 12.66$, $p < .001$, while initial CC scores remained significant ($\beta = .32$, $p < .05$) once variation in verbal and nonverbal ability had been adjusted for.

The fact that the typically developing group improved considerably on both CC measures might imply, paradoxically, that children develop a more pronounced local processing bias over time. Other factors, such as children's maturing nonverbal and executive skills, however, are most likely driving this developmental change. Indeed, performance on both CC measures has been linked previously to concurrent verbal and nonverbal ability (Wechsler, 1999; Witkin et al., 1971), and early nonverbal ability (but not verbal ability) was longitudinally predictive of later performance on the Pattern Construction task, $r(29) = .51$, $p < .005$, and the CEFT, $r(29) = .33$, $p = .06$, in the current sample of typical children. Analyses also revealed a trend for early EF aggregate scores to be associated with later Pattern Construction performance, $r(29) = .32$, $p = .07$, and CEFT performance, $r(29) = .30$, $p = .09$, consistent with the possibility that typically developing children's improving executive skills might enable children to better resist interference from the overall Gestalt and therefore rapidly locate either the hidden figure (in the case of the CEFT) or the blocks necessary to reconstruct the design (in the case of the Pattern Construction task). Since the scores on both CC measures do not represent "pure" indices of local processing, the two CC variables (children's CEFT and Pattern Construction scores) were regressed on nonverbal ability and EF at each time point, and the unstandardized residuals for each variable were saved. For each individual, these residual scores represent the difference between his or her observed score and what would be expected given his or her nonverbal and executive ability. The saved residuals for each variable were then converted to standard scores and averaged to form an aggregate CC score for each time point. These aggregate scores were used in subsequent analyses to address the question of universality of enhanced local processing skills in autism.

Multiple Cognitive Atypicalities at the Individual Level

The results at the group level demonstrate that children with ASD do in fact display the cognitive profile proposed by Happé, Ronald, et al. (2006) and that this profile persists across time. Next, I examined whether *individual* children with ASD showed this profile at both time points.

To examine the universality of cognitive atypicalities, the number of children with ASD that displayed an "atypicality" was calculated for each aspect of cognition using the modified t test developed by Crawford and Howell (1998). This one-tailed test is well suited for comparing single cases to small comparison groups since it treats the statistics of the comparison sample as statistics rather than as population parameters and further provides excellent control over Type I error rates. These authors use Sokal and Rohlf's (1995) formula:

$$t = \frac{X_1 - X_2}{S_2\sqrt{(N_2+1)/N_2}},$$

where X_1 is an individual ASD child's score, X_2 and S_2 are the mean and standard deviation of scores from the typically developing group, and N_2 is the comparison group sample size. Following Crawford and Howell (1998), the *p* value generated by each test is taken to be an estimate of the atypicality of an individual's score. For example, a *p* value of .15 indicates the proportion of the comparison group who would receive a score of similar or greater magnitude than the score obtained for a particular individual. For the purposes of this study, an individual's aggregate score for each of the three domains was classified as "atypical" if the *p* value fell below .15. Note that this definition is functionally similar to previous definitions of an atypicality (Lezak, 1995; see Pellicano, 2007) in which a score is considered to be atypical if it exceeds 1 *SD* above/below the mean score of the typically developing group. Venn diagrams illustrating the results can be found in Figure 1.

At Time 1, 27 of 37 children with ASD (73% of the group) scored below the cutoff ($p < .15$) on the ToM aggregate, 24 children (65%) showed an impairment in EF, and remarkably, all but 1 child (97%) displayed weak CC. How many children showed atypicalities in *all three cognitive domains* at intake (cf. Happé, Ronald, et al., 2006)? More than half of the ASD group (59%) showed co-occurring atypicalities in ToM, EF, and CC. Five children (14%) showed poor ToM and weak CC, 2 children (5%) showed atypicalities in both EF and CC, and the remaining 7 children (19%) displayed weak CC alone (see Figure 1a). One additional child (3%) showed no atypicalities at Time 1.

At Time 2, 26 of 37 children with ASD (70%) fell below the cutoff on the ToM aggregate, 20 children (54%) showed poor EF, and 18 children (49%) showed enhanced local processing. Only 7 children (19%) showed multiple atypicalities in ToM, EF, and CC at Time 2 (see Figure 1b). Of the remaining 30 children, a substantial portion (11 children; 30%) showed joint problems in ToM and EF, 6 children (16%) displayed weak CC combined with poor ToM, 1 child (3%) showed weak CC and poor EF, 2 children (5%) showed ToM difficulties in isolation, 4 children (11%) showed only weak CC, and 1 child (3%) showed EF difficulties alone. Surprisingly, 5 children (13%) showed *no* cognitive atypicalities at follow-up. Of these 5 children, 4 had a clinical diagnosis of autism and 1 child had a diagnosis of PDD–NOS, and 4 of 5 children showed sufficient behavioral symptoms at follow-up to meet the cutoff for autism on the ADOS–G (Lord et al., 1999). Among the 22 children who showed all three atypicalities at Time 1, 5 children continued to display this profile at Time 2, 11 children showed persistent difficulties in ToM and EF, 2 children showed atypicalities in ToM and CC, 3 children showed ToM

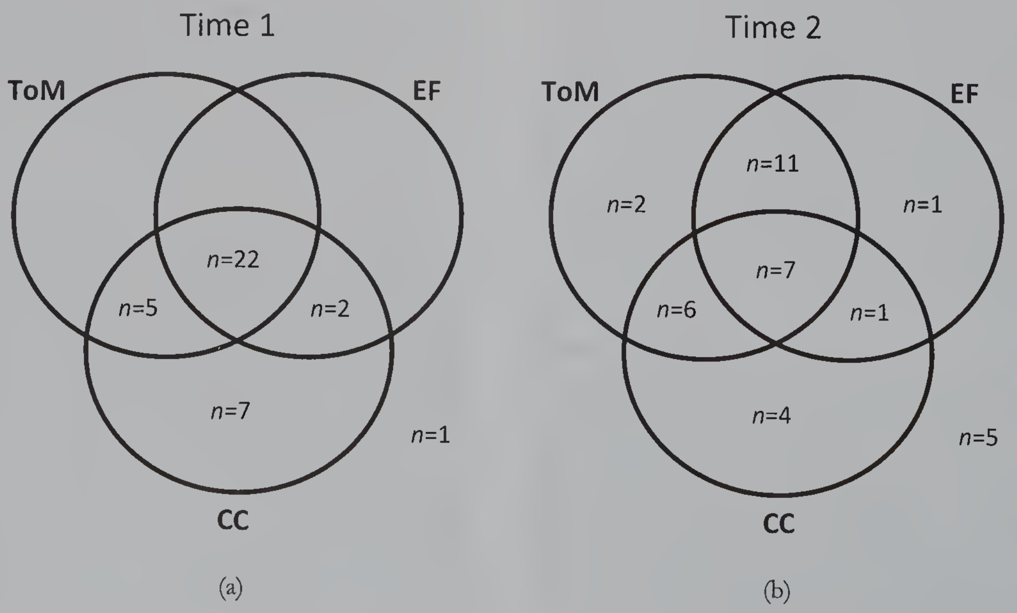

Figure 1. The overlapping circles in these Venn diagrams represent the potential combinations of atypicalities in ToM, EF, and CC. The region in the center represents co-occurring atypicalities in all three cognitive domains: the putative cognitive phenotype of autism (cf. Happé, Ronald, & Plomin, 2006). The numbers inside each region represent the number of children with an autism spectrum disorder condition showing that particular atypicality alone or combination of atypicalities at (a) Time 1 and (b) Time 2.
Note. ToM = theory of mind; EF = executive function; CC = central coherence.

problems in isolation, and 1 child showed no atypicalities.

It is possible that, among those children who failed to demonstrate atypicalities in one or more cognitive domains, such atypicalities were in fact present in some or all of these children, albeit to a lesser degree. To investigate this further, additional analyses were carried out using a less conservative definition of atypicality, where an individual's aggregate score for each cognitive domain was identified as ''atypical'' if the p value fell below .50. (Note that this is a lenient definition of atypicality since the p value estimates the point at which 50% of the typical population would obtain scores lower than the score obtained for a particular individual; cf. Crawford & Howell, 1998.) According to the main universality analyses using the conservative criterion ($p < .15$; see Figure 1), at Time 1, 10 children showed no problems in ToM, 13 children demonstrated no EF difficulties, and 1 child failed to show weak CC. Subsequent analyses using the more lenient criterion ($p < .50$) revealed that all of these cases showed atypicalities in these domains (ToM: all cases $\leq p = .48$; EF: all cases $\leq p = .43$; CC: all cases $\leq p = .43$). At Time 2, the central, more conservative analyses revealed that 11 children showed no ToM difficulties, 17 children showed no EF problems, and 19 children failed to show weak CC. Again, when the more lenient criterion was applied, all children were classified as atypical on each aspect of cognition (ToM: all cases $\leq p = .38$; EF: all cases $\leq p = .46$; CC: all cases $\leq p = .45$), suggesting that the entire sample of children with ASD appeared to show the putative cognitive profile, albeit in subtle form.

Discussion

Developmental Persistence

Relative to age- and ability-matched typically developing children, children with ASD showed difficulties in false-belief understanding, problems with higher order planning and cognitive flexibility together with capabilities in processing local information *at both time points*. This finding supports Happé, Ronald, et al.'s (2006) claim that there is a specific profile of coexisting cognitive atypicalities in autism, which shows continuity with development. Yet testing the claims of Happé, Ronald, et al.'s multiple-deficits model required not only analysis of the group as a whole but also examination of the performance of individual children with ASD. Such analysis demonstrated that the putative profile was not universal at either time point and became markedly less pervasive at follow-up. At intake, weaknesses in false-belief attribution and aspects of EF were found to be less pervasive than atypicalities in CC, resulting in just over half of the ASD group displaying coexisting atypicalities in all three domains. At follow-up, a dramatically different pattern emerged: None of the atypicalities were entirely pervasive, and only a minority of children displayed the complete profile. Inspection of the group means at Time 2 revealed that the distributions overlapped greatly, but particularly so for the CC tasks. Indeed, group differences on the CEFT were attenuated at Time 2, and had disappeared altogether on the Pattern Construction task.

Measurement issues might have contributed to the failure to demonstrate the universality of this cognitive profile in two ways. First, the Time 2 analyses on ToM were complicated by the presence of ceiling effects in the typically developing group, which could have influenced the magnitude of the group difference and, in turn, the number of individual children with ASD showing ToM difficulties. Even in the event that this was true, it is difficult to see how this explanation alone could explain the minority of children with ASD ($n = 7$) showing all atypicalities at follow-up since this ceiling effect should not have affected the results concerning atypicalities in EF and CC, which together accounted for less than half of the group.

Second, the cognitive measures were matched neither for discriminative power nor for reliability (cf. Chapman & Chapman, 1973), rendering it possible that the tasks were not sufficiently sensitive to detect subtle cognitive atypicalities. Internal consistency was moderate to high for cognitive tasks, which remained stable across time points, and there was good convergent validity for each cognitive domain at intake and follow-up. Reliability was not evaluated for executive measures, which has been reported to be low in typical samples (e.g., Bishop, Aamodt-Leeper, Creswell, McGurk, & Skuse, 2001) and high in autism samples (e.g., Ozonoff, 1995). The results of these analyses therefore should be treated with some caution.

Despite these limitations, the fact that the majority of children failed to show multiple cognitive atypicalities at follow-up combined with the presence of some children who showed *no* cognitive atypicalities is problematic for Happé, Ronald, et al.'s (2006) candidate multiple-deficits account, which attempts to provide an integrated causal explanation for the pathogenesis of autism. It is noteworthy that analyses using a more lenient definition of atypicality demonstrated that *all* children with ASD showed the putative cognitive profile, which is encouraging for Happé, Ronald, et al.'s account. It is worth emphasizing, however, that according to this lenient definition of atypicality ($p < .50$), one should expect to find 50% of individuals in the population from which the comparison sample was drawn also to receive a score of similar or greater magnitude than that observed for individuals with ASD (Crawford & Howell, 1998). In such instances, one would be cautious in classifying these typical children as showing an atypicality, and therefore one must be equally cautious of doing so in the case of ASD.

Certainly, the findings from these supplementary analyses serve to highlight the challenges in defining atypicality, especially when examining individuals with developmental conditions, whose cognitive skills are unlikely to be "all or none." Rather than "atypicality" being conceptualized categorically, it might be beneficial to conceive of the three cognitive domains as dimensions located (orthogonally) within a multivariate space (Happé & Ronald, 2008; Happé, Ronald, et al., 2006). The extent to which a person with autism shows a particular cognitive atypicality therefore should vary according to the place he or she occupies on that dimension, which in turn, should relate directly to the degree and nature of the behavioral symptoms it purports to explain. This elaboration is appealing as it could potentially account for the phenotypic heterogeneity in autism. It would be of interest, therefore, to demonstrate empirically that individual differences in cognitive skills are indeed significantly related to individual differences in specific aspects of the behavioral phenotype—both concurrently and longitudinally. Despite its appeal, it nevertheless remains a challenge for this account to explain the absence of the suggested cognitive atypicalities in 4 children with ASD who have sufficient behavioral symptoms at follow-up. It is plausible that the emergence of cognitive atypicalities at some point in development could be sufficient to cause behaviors severe enough to persist beyond the cognitive atypicalities themselves.

Developmental Progress in Autistic Children's Cognitive Skills

An understanding of such putative processes necessarily demands a fuller developmental perspective than is currently offered. The second main finding from this study was that were considerable developmental improvements in autistic children's ToM and EF, but no changes in local processing. Children with ASD made substantial progress in their false-belief understanding over the 3-year period to the extent that more than one third of the group succeeded on advanced false-belief tasks at follow-up. These findings present a more optimistic picture of autistic children's developing ToM than earlier longitudinal studies, which reported negligible progress in children's false-belief understanding (Holroyd & Baron-Cohen, 1993; Ozonoff & McEvoy, 1994). Notably, children in these early investigations were older and less able than participants sampled both in the current study and in two recent longitudinal studies, which also demonstrated improvements in some aspects of children's ToM skills (Serra et al., 2002; Steele et al., 2003), highlighting the possibility that improvements, should they occur, might be most apparent early on during development (cf. Yirmiya, Erel, Shaked, & Solomonica-Levi, 1998). The greater emphasis in recent years on early behavioral intervention for young children with autism might also account for the greater developmental progress reported in more recent studies compared to earlier ones.

Children's planning capacity also improved significantly over the 3-year period—at a strikingly faster rate than that of typically developing children. These findings go against the two existing prospective studies on EF in autism, which reported progress in EF neither in very young children with autism (Griffith et al., 1999) nor in adolescents with autism (Ozonoff & McEvoy, 1994). Again, differences in sample selection could explain the opposing pattern of results since both of these studies included individuals with autism less able than the sample of autistic children assessed here. Interestingly, and akin to the current findings, Happé, Booth, Charlton, and Hughes (2006) found that the EF performance of older participants with autism (*M* age = 13 years 2 months) surpassed that of younger children (*M* age = 9 years 2 months), suggestive of age-related gains in EF. Furthermore, although the authors did not find evidence of specific problems in planning ability, they nonetheless showed that this EF component showed the greatest age-related improvements in the autism group. The current longitudinal data strengthen Happé, Booth, et al.'s cross-sectional findings, and indicate that EF problems become *less marked with age*, at least for cognitively able children with autism.

Several factors might explain this boost in ASD children's ToM and executive skills over the 3-year period. The first of these is language. Regression analyses showed that verbal ability contributed significant variance in later ToM scores over and above variance already accounted for by early ToM performance. The important influence of language during children's developing ToM is consistent with an abundance of cross-sectional (e.g., Fisher, Happé, & Dunn, 2005; Happé, 1995) and some longitudinal (Steele et al., 2003; Tager-Flusberg & Joseph, 2005) work, showing that language ability, and especially grammatical ability, is significantly related to autistic children's performance on ToM tasks. Alongside these findings, the current data provide firm evidence that early language skills might play an important role in facilitating autistic children's understanding of the representational nature of mind.

Early verbal ability was, however, unrelated to children's developmental improvements in planning ability. This finding was unexpected since there are both empirical and theoretical reasons to anticipate a link between language and children's developing executive skills. Russell (1996) argued that (internal) language ability plays a key role in executive control over action. Specifically, success on executive tasks, such as the Tower of London task, should be bolstered by the use of inner speech, that is, if the child forms a *verbal representation* of the sequence of moves necessary to solve the problem in the minimum number of moves. Two studies have shown experimentally that reduced executive control in autism might indeed result from an inherent failure to use language to regulate and control one's actions (Joseph, Steele, Meyer, & Tager-Flusberg, 2005; Whitehouse, Maybery, & Durkin, 2006). If language is integral to success on EF tasks, then it is puzzling that early language skills were unrelated to developmental *improvements* on such tasks in the current study. Perhaps children's use of compensatory strategies, which might be nonverbal in nature, becomes increasingly practiced over time, affording gradual gains in executive control.

The second factor that could explain the enrichment in autistic children's developing ToM and EF is social contact (Hughes, 1998b). Work with typically developing children shows that early peer interactions, particularly those involving pretense, foster the development of ToM (Hughes & Dunn, 1998; see Dunn, 2004, for a review). Likewise, social relations are likely to influence children's developing executive skills since negotiating everyday social interactions requires children to regulate their own behaviors (Luria, 1966; see also Hughes, 1998b). The majority of autistic children in the current study attended mainstream classrooms ($n = 34$), and therefore encountered frequent (and varying) models of age-appropriate social interactions. Evidence suggests that cognitively able children with autism seek out their nonautistic peers (Sigman & Ruskin, 1999). Engaging with more advanced social partners on an everyday basis therefore might have bootstrapped the development of these children's mental-state reasoning and executive control (Vygotsky, 1978). Indeed, increased social contact during this period of development might also account for the *enhanced* rate of acquisition of EF skills compared to typical children. EF shows a protracted development trajectory, which renders it especially susceptible to environmental influences. Recent findings suggest that EF skills are indeed malleable in young children (Diamond, Barnett, Thomas, & Munro, 2007). It therefore remains possible that attendance in mainstream schools provided an enriched social environment with ample opportunities for autistic children to "exercise" their EF skills, therefore boosting the rate of acquisition of such skills. Identifying which aspects of social relations, if any, partially mediate the development of children's EF and ToM skills is a worthy line of investigation since this should have implications for the remediation of atypicalities in these cognitive domains.

A third reason for the improvements in EF and ToM is that the development of these functions is in fact inextricably linked. There is strong evidence that ToM and EF are closely tied in typically developing children (e.g., Carlson & Moses, 2001; Hughes, 1998a, 1998b) and in autism (e.g., Pellicano, 2007). The nature of this link, however, is controversial. Some authors have proposed that executive skills are a prerequisite for the later development of ToM (Moses, 2001; Russell, 1996), while others claim that a representational understanding of mind is necessary for the later control of goal-directed, purposeful action (Perner & Lang, 1999). Further still, the parallel progression of ToM and EF might be due to a third factor: that both skills are mediated by adjacent structures in the prefrontal cortex (Ozonoff et al., 1991). Research on the overlap between these two domains in autism is scarce yet analysis of the longitudinal links between EF and ToM in the current sample of children with ASD (see Pellicano, 2010) points toward a developmental relationship in one direction only. Earlier EF skills were found to be longitudinally predictive of change in autistic children's ToM test performance, independent of age, verbal ability, nonverbal ability, and early ToM skills but there were no significant predictive relations in the opposite direction. Akin to work with typically developing children, these findings find favor with Russell's account that EF plays an important role in the advancement of autistic children's ToM skills (see also Pellicano, 2007). Nevertheless, the possibility of a functional link between EF and ToM is potentially inconsistent with Happé, Ronald, et al.'s (2006) model, which considers the co-occurring cognitive atypicalities in autism to be independent and genetically distinct, and is therefore unlikely to support any notion of one atypicality emerging from another.

Despite significant improvements in ToM and executive skills, children experienced no changes in local processing over the 3-year period. Children with ASD were no quicker to find the hidden figure on the CEFT than they were 3 years earlier, and their scores on the Pattern Construction task failed to change over time. This lack of change is in striking contrast to the significant gains made by typically developing children evidenced on both weak CC tasks. Could the lack of an improvement be explained by a ceiling effect in the ASD group? This explanation might account for children's CEFT performance, but it is unlikely that a ceiling effect could account for children's equally limited improvement on the Pattern Construction task since the majority of children's scores were well below the maximum score.

One alternative explanation is that the development of local processing takes strikingly different courses in autism and typical development. This suggestion is consistent with one competing account of perceptual atypicalities in autism, enhanced perceptual functioning (Mottron & Burack, 2001), which proposed that such peaks derive from the overdevelopment of basic perceptual processes, including local processing. Rather than being present from birth, superior local processing emerges early on during the course of development in response to diminished processing of higher order operations. In line with Mottron and Burack's (2001) claim, the current findings suggest that these skills are early emerging and initially accelerated in autism. Over time, it appears that the trajectories of children with ASD and typical children converge as typical children's performance on tasks tapping local processing "catches up" to that of autistic children although potentially via a different route (see Results for details).

The current data also highlight the possibility that the developmental trajectory of local processing in autism might be qualitatively distinct from the trajectories of other, higher cognitive domains (ToM and EF), which appear to mature later and progress somewhat in parallel. Do these findings fit with Happé, Ronald, et al.'s (2006) theoretical position? In its current form, the model says little about the ways in which these cognitive atypicalities unfold with development and which sort of factors influences their progression. The possibility of distinct developmental trajectories for some aspects of cognition might be taken as evidence to support a fractionable cognitive characteristics account (Happé & Ronald, 2008). Although Happé, Ronald, et al. hinted at the possibility of potential "interactions" between cognitive domains, the nature of any such interactions remains unspecified. Further analysis of the current longitudinal data (see Pellicano, 2010) suggest that interactions do in fact exist, specifically in which early domain-general skills (EF and CC) play a crucial role in shaping the developmental trajectory of autistic children's emerging ToM. Certainly, further elaboration of Happé, Ronald, et al.'s model is required to explain the continuities and discontinuities in the development of core cognitive skills, the specific *developmental* relationships between cognitive domains, and the potential factors (e.g., verbal ability, social interaction; Hughes, 1998b) that might mediate or moderate such development.

Conclusion

This is the first prospective study to investigate the development of *multiple* cognitive atypicalities in ASD. Several tasks tapping ToM, EF, and CC were administered to the same samples of children at two different time points separated by 3 years. The findings showed that cognitively able children with ASD, as a group, show coexisting atypicalities in important aspects of ToM, EF, and CC, relative to typically developing comparison children, and that this profile persists over time—precisely in the way Happé, Ronald, et al. (2006) proposed. Their multiple-deficits model goes far beyond previous single-deficit models by invoking several core underlying atypicalities that, together, underpin the symptoms of autism—arguably, a much more realistic position given the heterogeneity present in the condition. Yet not all children showed this particular cognitive profile. Nor did children's cognitive skills remain static and unchanging. In fact, they experienced considerable gains in those aspects of cognition that typically present them with the most difficulty—progress that is encouraging and perhaps unsurprising in developing cognitive systems, but is nonetheless difficult to predict from Happé, Ronald, et al.'s model in its current form. Whether this pattern of findings will be similar for children with autism who have additional learning difficulties remains a crucial question for future research. The current findings nevertheless stress the need for theorists to take seriously the *developing* cognitive phenotype of autism.

Gender Differences in Spatial Ability of Young Children: The Effects of Training and Processing Strategies

David Tzuriel and Gila Egozi
Bar Ilan University

A sample of 116 children (*M* = 6 years 7 months) in Grade 1 was randomly assigned to experimental (*n* = 60) and control (*n* = 56) groups, with equal numbers of boys and girls in each group. The experimental group received a program aimed at improving representation and transformation of visuospatial information, whereas the control group received a substitute program. All children were administered mental rotation tests before and after an intervention program and a Global–Local Processing Strategies test before the intervention. The results revealed that initial gender differences in spatial ability disappeared following treatment in the experimental but not in the control group. Gender differences were moderated by strategies used to process visuospatial information. Intervention and processing strategies were essential in reducing gender differences in spatial abilities.

Spatial ability has a vital role in our daily interaction with environment, such as navigation, recognizing and manipulating objects, academic tasks, and recalling locations. Spatial ability is one of the several relatively autonomous human intellectual competencies (Gardner, 1983) and is considered essential to mathematics and scientific thinking (Delgado & Prieto, 2004), performance on standardized tests (e.g., the SAT; Casey, Nuttall, Pezaris, & Benbow, 1995), representing and manipulating of information, and problem solving. Proficiency in visuospatial ability has long been associated with success in cognitively demanding educational tracks and occupations such as engineering, architecture, physics, chemistry, and surgery (e.g., Snow & Yalow, 1982; Sorby & Baartmans, 2000) and is a salient characteristic of physical scientists (Gohm, Humphreys, & Yao, 1998; Humphreys, Lubinski, & Yao, 1993). Visuospatial ability is not routinely taught by schools and thus is not often developed and assessed in ways that influence students' educational and career plans (Webb, Lubinski, & Benbow, 2007). Adding spatial ability to identification procedures of talented students (currently restricted to mathematical and verbal ability) could uncover a neglected pool of math–science talent and holds promise for refining our understanding of intellectually talented youth.

Gender differences in spatial ability are well documented in the scientific literature (e.g., Coluccia & Louse, 2004; Halpern, 2007; Kimura, 1999; Levine, Vasilyeva, Lourenco, Newcombe, & Huttenlocher, 2005; Voyer, Voyer, & Bryden, 1995). Early researchers in this area have traditionally reported a male advantage over female on standard tests of spatial ability, at least after adolescence (Maccoby & Jacklin, 1974). Recent research, however, showed that gender differences emerge around the time children enter kindergarten or begin first grade, which may be as early as children can reliably perform tasks that assess visuospatial abilities. Levine, Huttenlocher, Taylor, and Langrock (1999) found that, on average, preschool boys are more accurate than girls at spatial tasks that measure that accuracy of spatial transformations ($d = .31$) and score higher on the Mazes subtest of the Wechsler Preschool and Primary Scale of Intelligence ($d = .30$). They concluded that gender differences in favor of boys are present on spatial tasks by age 4½.

Meta-analytic studies suggested that spatial ability is not a unitary construct, and that the magnitude of gender differences deeply depend on a task's demands (Coluccia & Louse, 2004; Kimura, 1999; Linn & Petersen, 1985; Voyer et al., 1995). However, those reviews provided substantial evidence that the largest and the most robust gender

---

differences arise on spatial tasks involving mental rotation, like the classical mental rotation test developed by Shepard and Metzler (1971). Gender differences in mental rotation tests are typically associated with some of the earliest disparities in strategies used by boys and girls in processing visual–spatial information (Cooper, 1976; Kramer, Leopard, Ellenberg, & Share, 1996). Recent studies with infants, using habituation techniques, demonstrated that already by the age of 3–5 months, there were gender differences in mental rotation (Moore & Johnson, 2008; Quinn & Liben, 2008). Quinn and Liben (2008) provided evidence showing that male infants were more likely than female infants to recognize as equivalent a two-dimensional figure rotated in the same way as was the figure shown during a familiarization phase. The male infants were also more likely than female infants to perceive a mirror image of that figure as novel. Similarly, Moore and Johnson (2008) demonstrated gender differences with 5-month-old infants using two-dimensional object representing three-dimensional object. The male infants discriminated the habituation objects from its mirror-image test objects whereas female infants treated both objects similarly. In both studies, the investigators conclude that in spite of the fact that gender differences in mental rotation are already apparent at infancy, more research should be carried out to explore the interacting factors that influence the development of mental rotation.

Several researchers reported that global–local strategies were inherently related to mental rotation performance (Bethell-Fox & Shepard, 1988; Bryden, George, & Inch, 1990; Johnson, 1990). Small effect sizes were reported for simple commonly used tasks whereas in more difficult tasks that require generating an image and maintaining it in working memory, results vary depending on the complexity of the image to be generated and the specific nature of the task, with observed differences ranging between *d* = .63 and *d* = .77 (Loring-Meier & Halpern, 1999). Mental rotation tasks that require maintaining a three-dimensional figure in working memory while simultaneously transforming it show very large gender differences, somewhere between 0.90 to 1.0 *SD* (Masters & Sanders, 1993; Nordvik & Amponsah, 1998), although some researchers have reported smaller effect sizes (Voyer et al., 1995).

Males' outperformance of females on measures of visuospatial abilities has been implicated as contributing to gender differences on standardized exams in mathematics and science (Halpern et al., 2007). An evolutionary account of gender differences in mathematics and science (e.g., Geary, 2007; Gur & Gur, 2007; Haier, 2007) supports the conclusion that although gender differences in math and science performance have not directly evolved, they could be indirectly related to differences in interests and specific brain and cognitive systems. Newcombe (2007) challenged the evolutionary approach, first, by showing logical inconsistencies and gaps in biological sex differences research and, second, by demonstrating that these differences are not immutable and can be eliminated by proper intervention.

In the present study, we address four important interrelated questions: (a) Do young children in first grade show gender differences on mental rotation tasks at an appropriate level of difficulty for their age? (b) To what degree does training of representation and transformation of perceptual stimuli, by viewing them from different perspectives, reduce initial gender differences? (c) Is the magnitude of the hypothesized gender differences influenced or moderated by global versus local strategies of representing and transforming visuospatial information? (d) What are the interactive effects of gender, training, and task difficulty (degree of rotation and test level) on performance of mental rotation tasks?

For the purpose of this study, we constructed a mental rotation test, which is based on the *Mental Rotation* subtest of the *Cognitive Modifiability Battery* (CMB; Tzuriel, 1995, 2000a, 2000b; Tzuriel & Egozi, 2006) and an intervention program aimed at training global strategies of representing and transforming of spatial information based on Wheatley's (1996) ''Quick Draws'' activities. According to Piaget and Inhelder (1956), these abilities are vital components in mental rotation performance. Representing and transforming spatial information requires to some degree an extension of working memory capacity proved to be essential for mental rotation performance. Coluccia and Louse (2004) in their extensive meta-analytic review have reached a conclusion that gender differences in spatial orientation emerge only when tasks require a high load of visuospatial working memory. Thus, males would show better performance in spatial orientation because of their larger visuospatial working memory span. When the orientation task does not involve a high load in visuospatial working memory, gender differences would disappear. Similarly, Feng, Spence, and Pratt (2007) showed that improvement in performance on a mental rotation task, following training composed of playing an action video game, was associated with improvement in spatial attention. Furthermore, following training, females showed higher improvement than males on both spatial attention and mental rotation tasks. Vasta, Knott, and Gaze (1996) showed also that gender differences were eliminated by carefully conceptualized training.

In congruence with other researchers (Feng et al., 2007; Newcombe, Mathason, & Terlecki, 2002), our claim is that it is more important to determine whether gender differences may be reduced or eliminated by training than merely documenting them. Baenninger and Newcombe (1989) reported in their meta-analytic study that spatial ability can indeed be improved with training, with effect sizes ranging from $d = .40$ to $d = .80$, depending on the length and specificity of the training. However, no differential improvements were reported for boys and girls. A more recent meta-analysis of the effects of training and experience on spatial skills confirms the earlier findings (Marulis, Lui, Warren, Uttal, & Newcombe, 2007). However, the effects of training were similar for males and females; that is, both groups benefited about equally from the training; no evidence was found to show that the gap was closed or widened by training.

In a recent study by Tzuriel and Egozi (2006), gender differences in mental rotation were investigated among 5- to 6-year-old kindergarten children. The objectives were to investigate the interactive effects of gender, treatment, and task characteristics on spatial abilities tasks using a *dynamic assessment* (DA) procedure (Haywood & Lidz, 2007; Lidz & Elliott, 2000; Sternberg & Grigorenko, 2002; Tzuriel, 2001). The treatment was composed of teaching children to preserve the whole pattern of a model at different positions in space. This teaching strategy focuses on a global-holistic approach based on pattern conservation of the model and rotating it in the space as a whole unit, without fragmenting its components. Clinical experience showed the global-holistic strategies to be more efficient than analytic strategies, as children could use global-holistic strategies to circumvent the difficulty of defining verbally the problem's components. A verbal analytic strategy was given as a secondary strategy to support children who might have difficulty with the holistic approach. The findings revealed a significant improvement in mental rotation in both gender groups. A differential treatment effect on boys and girls was evident, however, when task characteristics (e.g., degree of rotation, pattern complexity) were involved. Contrary to the hypotheses, *boys responded more effectively to intervention at difficult levels of the tasks and improved their mental rotation more than did girls.* The differential improvement of boys and girls was attributed to different strategies used by them (e.g., global), as evidenced by clinical observations during the teaching phase. In spite of the fact that all children were offered similar strategies, boys tended to use a global approach based on *conservation of patterns and rotation of the unit as a whole,* whereas girls showed a detailed analytic approach based on verbalization of location.

These findings and the clinical evidence showing the effectiveness of a global-holistic perceptual approach in representing visuospatial information were the basis of the current study. Unlike the short 1-hr intervention (teaching phase of a DA procedure) used earlier (Tzuriel & Egozi, 2006), in the current study we used a more intensive intervention approach composed of eight small group sessions (45 min each).

Following Tzuriel and Egozi's (2006) study, our main hypothesis was that initial gender differences in mental rotation will be reduced by the use of adequate training based on developing cognitive processing strategies of representation and transformation of visuospatial information. We also hypothesized that boys will show higher global strategies in processing visuospatial tasks than girls who will tend to show local strategies, and that the initial gender differences will disappear when Global–Local Processing Strategies (GLPS) are considered. With regard to the intervention program, we hypothesized that it would be more effective for high-level than low-level tasks (i.e., as degree of rotation increases).

Method

Participants

The sample was composed of 116 first-grade children (58 girls and 58 boys), recruited from Israeli public schools. Most children were of Jewish ethnic origin (89.66%) and the rest were Israeli-Arabs (10.34%). Children ranged in age from 6 years to 7 years 2 months (M = 6 years 7 months, SD = 3.71 months), with no significant age differences between boys and girls, $F(1, 113) = 1.81$, *ns*. All children were right-handed, with no history of developmental, neurological, or learning problems. The reason for including only right-handed children is based on recent neurological research showing different hemispheric activity among left- and right-handed individuals (Kim et al., 1993). Some researchers suggest controlling this variable when studying gender differences in spatial ability (e.g., Kramer et al., 1996). The sampling process was carried out in three stages: (a) random selection of 10 of 34 public primary schools whose principals agreed to apply for an intervention program for the development of spatial abilities, (b) random selection of one first-grade class in each school, and (c) a random selection of 6 boys and 6 girls in each class. The parents were required to consent to the inclusion of their child in the study and provide basic information on the child's developmental history. During data gathering, 4 of the original sample of 120 children could no longer participate in the study because their families moved from the area.

A sample of 3 boys and 3 girls from each class were randomly assigned to experimental and control groups. The experimental group consisted of 60 children (30 each, boys and girls) and the control group consisted of 56 (28 each, boys and girls). Both groups were similar on socioeconomic status (SES) indices of parent occupation, $\chi^2(4) = 3.10$, *ns*, and years of education, $\chi^2(4) = 3.68$, *ns*. In both groups, about 50% of the parents graduated high school and held a professional occupation. In view of Levine et al.'s (2005) findings that gender differences are sensitive to SES differences, the similarity of the experimental to the control group in the current sample seems to be satisfactory. No significant differences were found between the groups on a composite score of the WISC–R95 Vocabulary and Concept Formation subscales, $F(2, 112) = .58$, *ns*.

Measures

Spatial Relations (SR) subtest from the Primary Mental Abilities–Children's Version (Thurstone & Thurstone, 1965). The SR is a standard measurement for the ability to visualize rotated objects in two-dimensional space and to identify the relation among them. The SR is composed of 27 items and four examples. In each item, the child is presented with a model figure that is a part of a square and has to determine which of the four given alternatives completes the square. The alternatives are positioned so that children must mentally rotate the parts to complete the square. A score of 1 is given for each correctly solved item.

Although standardized administration of the SR is in groups, with a time limit of 4 min, in the present study it was administered individually and without a time limit, to avoid test stress and anxiety. Johnson and Meade (1987) reported a split-half reliability of .89, using the Spearman–Brown's formula among children in Grades 1–4. Correlations with other spatial ability tests ranged from .44 to .63.

The Windows Test (WT). Construction of the WT was based on the *Mental Rotation* subtest of the *CMB* (Tzuriel, 1995, 2000a, 2000b; Tzuriel & Egozi, 2006). Designed for children in first to fourth grades, it includes three difficulty levels (WT1, WT2, and WT3). In order to examine the adequacy of the WT for young children, a pilot study was carried out on Grade 1 children ($n = 32$). Based on the preliminary results where a floor effect was observed on the WT3 level, it was decided to administer only the first two levels (WT1 and WT2). For each test level, there are parallel versions that are administered in the pre- and postintervention phases, respectively.

In both test levels, children are presented with model figures of "houses with windows" arranged in a 3 × 3 patterns (nine windows); some windows are closed (blackened) whereas others are open. On turned-about houses, taking into account their rotation in space (see Figure 1), children are asked to mark the identical closed windows. The main difference between WT1 and WT2 is the clue for rotation, which is much more concrete and articulated in WT1 (red roof) than in WT2 (red basis line). For each level, there are 18 problems arranged according to the *degree of rotation* needed to solve the tasks (45°, 90°, and 180°), *complexity* (2, 3, and 4 closed windows), and *symmetry* (half are symmetrical and half are asymmetrical; see Figure 1). The unique design of the WT allows separate analyses of the child's responses according to test level, degree of rotation, complexity, and symmetry of the patterns. In the current study and for the sake of simplicity, we analyzed only the test level and degree of rotation.

Each correctly solved window is given a score of 1 (maximal score = 54). Cronbach alpha reliabilities in the pilot study were .79 and .82 for the WT1 and WT2, respectively. Test equivalency reliabilities for the WT1 and WT2 were .82 and .87, respectively. The Cronbach alpha reliabilities on the current Grade 1 sample, for pre- and postintervention, were: WT1 = .78 and .73, respectively; WT2 = .76 and .74, respectively. Test–retest correlations between pre- and postintervention in the experimental group were .60 and .66, respectively, and in the control group .79 and .79. Pearson correlations of the SR with WT1 and WT2 were .41 and .49, respectively. Construct validity was examined by analyzing the performance as a function of task

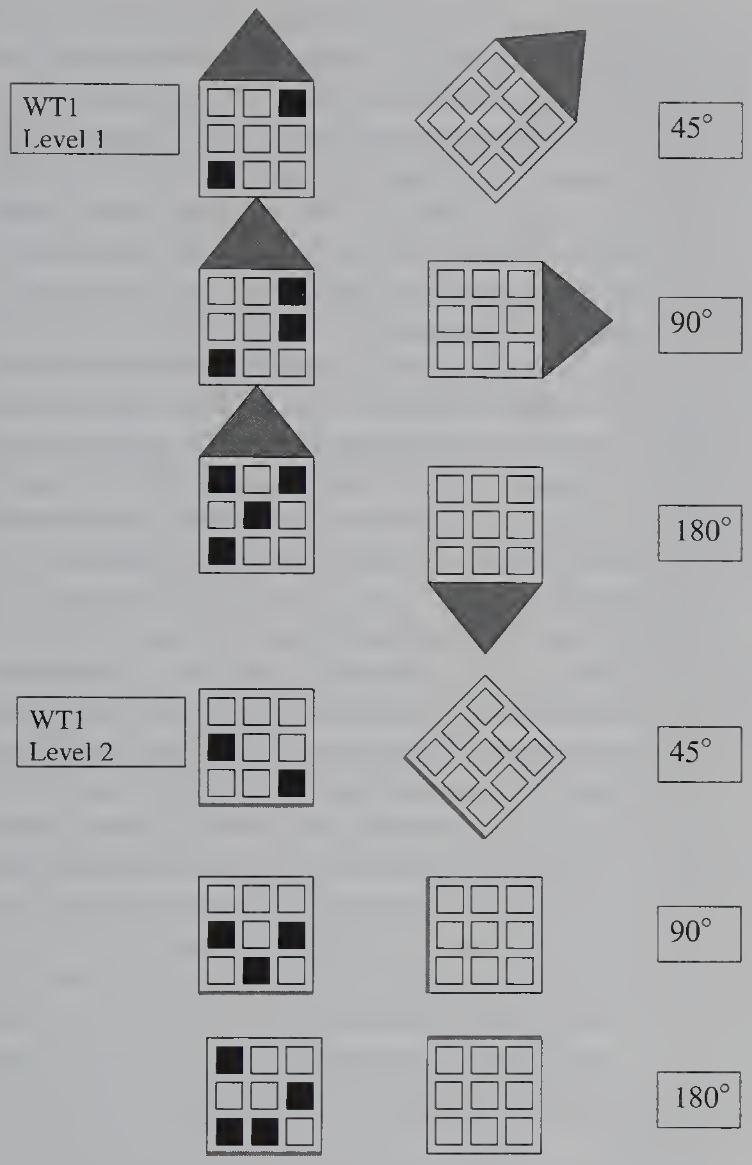

Figure 1. Mental rotation items from the Windows Test (WT).

characteristics. The findings of the pilot study showed clear linear decrease in performance as a function of degree of rotation, $F(2, 111) = 503.09$, $p < .001$, $\eta^2 = .90$; complexity level, $F(2, 111) = 28.53$, $p < .001$, $\eta^2 = .34$; symmetry, $F(1, 112) = 342.83$, $p < .001$, $\eta^2 = .75$; and test level (WT1, WT2), $F(1, 112) = 532.55$, $p < .001$, $\eta^2 = .83$. Findings on the initial composite WT scores, using the sample of the current study, also showed a significant performance decrease as a function of degrees of rotation, $F(2, 111) = 416.80$, $p < .001$, $\eta^2 = .88$, and test level, $F(1, 112) = 366.70$, $p < .001$, $\eta^2 = .77$.

Global–Local Processing Strategies. The GLPS (originally named Global–Local Judgment Tasks) was composed of 16 perceptual judgment tasks (stimulus cards) originally designed by Kimchi and Palmer (1982) for assessing visual–spatial processing styles among young children on a global–local dimension. Every stimulus card contained a standard figure at the top and two comparison figures at the bottom (see Figure 2). All the standard and comparison figures consisted of a global shape composed of local shapes. On each card, one of the comparison figures had the same global shape as the standard figure but comprised different local shapes; the other comparison figure had the same local shapes but was arranged in a different global shape. As can be seen in Figure 2, the global comparison figure is a square but comprised triangles. The local comparison figure, on the other hand, has the same local shapes (squares) but arranged into different global shape (triangle). For each stimulus card, children were asked to point out to one alternative out of two, which looked most like the standard, based on their first and immediate impression; clear instruction was provided that there are no right or wrong answers. The cards were presented one at a time in a random order, at a distance of approximately 60 cm from the child. To control for habitual orientation, half of the cards appeared with the global alternative on the right, while appearing on the left for the other half. A response was credited a score of 1 if the local comparison was selected and 2 if the global comparison was selected. The total score ranged from 16 to 32. Cronbach alpha reliabilities in a pilot study and in the current sample were .92 and .94, respectively.

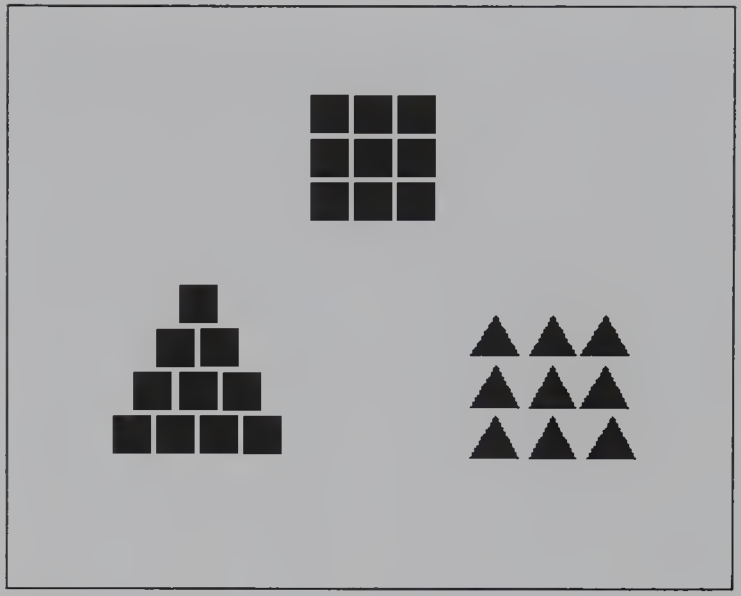

Figure 2. Example of a global–local task.

The "Spatial Sense" Intervention Program

The intervention program is based on Wheatley's (1996) "Quick Draws" activities, designed to promote spatial sense in the mathematics curriculum, with a focus on *representing and transforming spatial* *information,* according to the standards of the American National Council of Teachers of Mathematics.

The training program was composed of eight sessions, given once a week in a small group setting (3 boys and 3 girls). In each 45-min session, four flash cards were presented and discussed in the group. The activities were documented by the trainers and by children in special notebooks that served also for follow-up. Each lesson was composed of three stages. In the first stage, the trainer exposed flash cards to the children on a screen using an overhead projector. Each card was exposed three times, each time for 3 s. In the second stage, children were asked, after each series of card exposure, to draw what they saw. As the figure on the flash card is not observable while drawing, children must make their drawings using mental images they have constructed. The figures can be interpreted in many different ways (see Figure 3). In the third stage, the trainer guided the children, during group discussion, to look at the figures from different points of view. The children were encouraged to take their peers' perspectives and suggest the spatial imagery. The trainer allowed them to rotate the figures physically in order to demonstrate the image they perceived and drew. Typical descriptions given to the top picture shown in Figure 3, for example, were: a square with two trapezoids, two legs with shoes, a flower, a kite, a hat, a pyramid without top, a hallway, a room, a loudspeaker, back of a computer screen, and a popcorn box. Some of the descriptions were of a two-dimensional nature and some of three; some were constructed as an image of sections and others of joined segments. Typical descriptions given to the bottom picture shown in Figure 3, for example, were: hexagon with X, bow tie, two kites or diamonds, open envelope, a cube with some lines missing, and kind of a rollercoaster's seat.

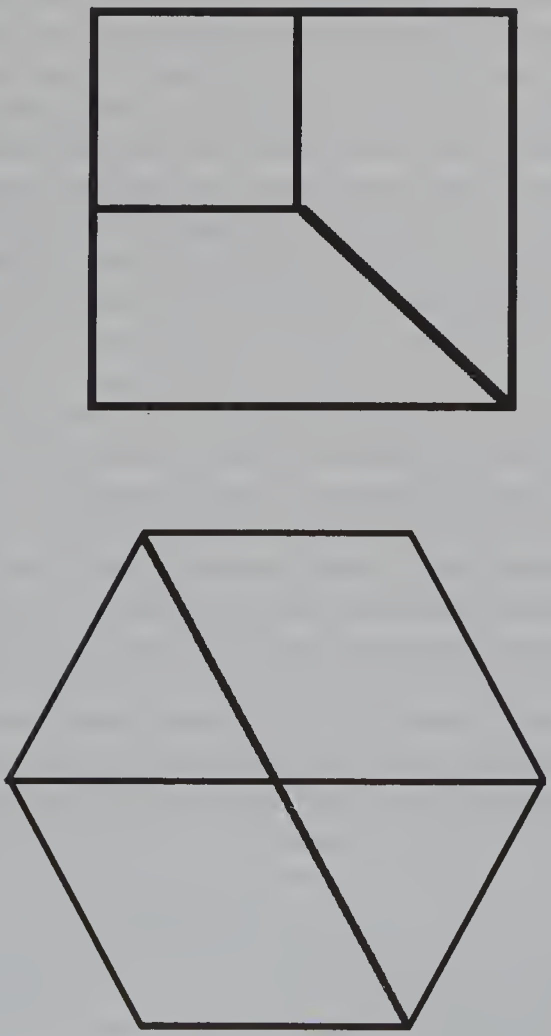

Figure 3. Training items from the "Spatial Sense" Intervention Program.

It should be emphasized that children were not directly trained to mentally rotate the figures but rather *to perceive the stimuli as a whole from different angles, retain them in their working memory, and flexibly conceptualize them as representing different objects.*

The original program is constructed for use with primary school children in a class situation. It includes 168 shapes arranged in seven levels. For the purposes of the current study, and based on a pilot study that verified their adequacy in terms of graphic-motor level, associative accessibility, and verbal possibilities, we selected 32 of the shapes found to be appropriate for use with first-grade children.

This choice of program was based on the studies of Wheatley and colleagues (Brown & Wheatley, 1997; Wheatley, 1990, 1991, 1997; Wheatley & Reynolds, 1999; Yackel & Wheatley, 1990), who showed that such activities improve children's ability to represent and transform spatial information. Analysis of the type of activities in the program shows that they help in expanding visuospatial working memory skills found to be crucial for mental rotation tasks (Coluccia & Louse, 2004). The choice of program is also appropriate to Tzuriel's (2000a, 2000b, 2001) approach, according to which concrete manipulations used with young children can serve as a "bridge" for complex mental manipulations.

Procedure

The procedure included three stages: preintervention, intervention, and postintervention. In the preintervention stage, children were individually tested on the SR test and WT (WT1, WT2), GLPS tasks, and Vocabulary and Concept Formation subtests, in that order. Graduate students administered the tests during 45 min in a quiet schoolroom.

Children in the experimental group participated in the intervention program for about a 3-month period. The control children participated in a substitute program for the same number of sessions, group structure, and setting. The control children were presented the same flash cards shown to the experimental group but without the short exposures, and were encouraged to copy the figures, individually, as accurately as possible. The control procedure was focused on pictographic and fine-motor skills but did not include teaching, group discussion, or guidance related to creation of visual imagery and spatial skills vital to mental rotations. Six trained graduate students who were not aware of the study's hypotheses administered the intervention and substitute programs. In the postintervention stage, 5 months after the preintervention phase, the SR test and WT (WT1, WT2) were administered again during one 30-min session. The tests in the postintervention phase were administered under the same conditions as the preintervention phase. Examiners who were not aware of the study's goals and the children's group assignment scored all tests.

Results

The Effects of Training Program on Gender Differences in Mental Rotation

The major objective of the current study was to investigate whether training in spatial abilities will moderate the effect of gender. In addition, we were interested in the relation between GLPS as a moderating factor of gender differences in spatial abilities and in the interaction effects of training with task characteristics (e.g., test level, degree of rotation) in moderating gender effects. Because of the complexity of the study's design, which includes five variables, we will report only interactions that involve gender, treatment, and time (pre- and postintervention). In Table 1, we present the pre- and postintervention scores of WT1, WT2, SR, and GLPS tests of boys and girls in the experimental and control groups. Preliminary correlation analyses of the study's variables were carried out, separately, for boys and girls (Appendix A) and for experimental and control groups (Appendix B). The findings indicate a similar correlation pattern for boys and girls and for experimental and control groups, except for the correlation of GLPS with SR Post, which was lower for girls than for boys.

Table 1

Pre- and Postintervention Windows Test (WT) and Spatial Relations (SR) Scores of Boys and Girls in the Experimental and Control Groups

		Experimental		Control	
Gender		Pre	Post	Pre	Post
WT Level 1					
Boys	*M*	46.63	50.07	45.89	47.14
	SD	4.41	3.06	3.98	3.77
Girls	*M*	43.93	49.83	41.86	43.89
	SD	5.38	2.63	5.49	5.62
WT Level 2					
Boys	*M*	39.00	45.00	37.07	38.79
	SD	5.99	4.58	6.72	5.34
Girls	*M*	34.77	43.17	34.14	35.11
	SD	6.07	4.43	5.35	5.98
SR test					
Boys	*M*	18.08	21.54	17.86	18.56
	SD	4.10	3.30	4.50	4.05
Girls	*M*	16.11	20.60	16.67	17.00
	SD	4.13	3.53	4.44	4.26

Analysis of WT scores. The effects of the training program were analyzed by a repeated measures nested design MANOVA of Treatment × Gender × Time × Test Level × Degree of Rotation ($2 \times 2 \times 2 \times 2 \times 3$), with treatment and gender as between-subjects factors and the last three variables as within-subjects factors; WT scores were the dependent variables.

The findings reveal a significant three-way interaction of Treatment × Gender × Time, $F(1, 112) = 4.73$, $p < .05$, $\eta_p^2 = .04$, as portrayed in Figure 4. Figure 4 shows that girls in the experimental group who scored much lower than boys did in the preintervention phase, improved their performance more than boys did and narrowed the gap in the postintervention phase. On the other hand, the girls in the control group scored equally lower than boys on both the pre- and postintervention phases. Post hoc analyses showed that in the experimental group, boys were higher than girls only in the preintervention phase, $t(1, 58) = 2.67$, $p < .01$, but not in the postintervention phase, $t(1, 58) = 1.11$, *ns*. In the control group, boys performed better than girls in both preintervention, $t(1, 54) = 2.55$, $p < .01$, and postintervention, $t(1, 54) = 2.83$, $p < .01$, phases. These findings support our main hypothesis by clearly showing that the intervention moderated and even canceled out the initial gender differences. Furthermore, in the postintervention phase, *the experimental girls performed significantly higher than the control boys*, $t(1, 56) = 3.79$, $p < .001$.

A significant three-way interaction of Treatment × Rotation × Time, $F(1, 112) = 13.51$, $p < .001$, $\eta_p^2 = .20$, shown in Figure 5, indicates that the gap between the experimental and control groups in the postintervention phase expands progressively with the increase in the degree of rotation. Post hoc analyses showed significant differences between the groups at 90°, $t(1, 114) = 6.15$, $p < .001$, and 180°, $t(1, 114) = 6.66$, $p < .001$, but not at 45°, $t(1, 114) = 1.29$, *ns*.

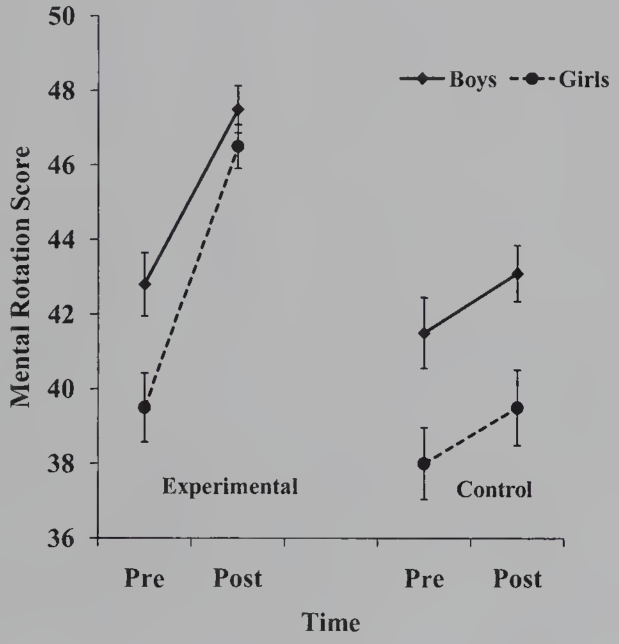

Figure 4. Pre- and postteaching performance on mental rotation among boys and girls in the experimental and control groups.

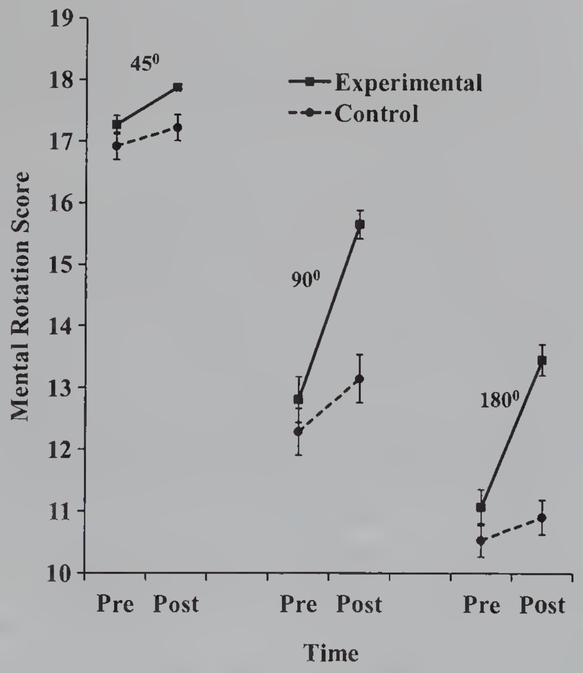

Figure 5. Pre- and postteaching performance on mental rotation in the experimental and control groups for each degree of rotation.

Another significant three-way interaction was of Treatment × Test Level × Time, $F(1, 112) = 8.69$, $p < .01$, $\eta_p^2 = .07$. This interaction, shown in Figure 6, indicates that the group differences in the postintervention phase were higher in Test Level 2 (WT2) than in Test Level 1 (WT1). Post hoc analyses showed that the experimental group scored significantly higher than control group in both Test Level 1, $t(1, 114) = 5.70$, $p < .001$, and Test Level 2, $t(1, 114) = 7.21$, $p < .001$. It is important to note that in Test Level 2, the experimental group showed much higher improvement, $t(1, 59) = 11.77$, $p < .001$, than the control group, $t(1, 55) = 2.31$, $p < .05$.

Analysis of SR test scores. We carried out separate analyses on the SR test as this test does not include task characteristics as the WT does. The means and standard deviations of boys and girls in the experimental and control groups are presented in Table 1. The effects of the training program were analyzed by a repeated measures MANOVA of Treatment × Gender × Time (2 × 2 × 2), with time as a within-subjects factor. The findings revealed a significant three-way interaction of Treatment × Gender × Time, $F(1, 112) = 71.80$, $p < .001$, $\eta_p^2 = .39$ (see Figure 7). As can be seen in Figure 7, gender differences in the experimental group decreased from pre- to postintervention, whereas in the control group, gender differences increased. Post hoc analyses showed that, in the experimental group, boys were higher than girls only in the preintervention, $t(1, 58) = 2.50$, $p < .01$, but not in the postintervention phase, $t(1, 58) = 1.19$, *ns*. In the control

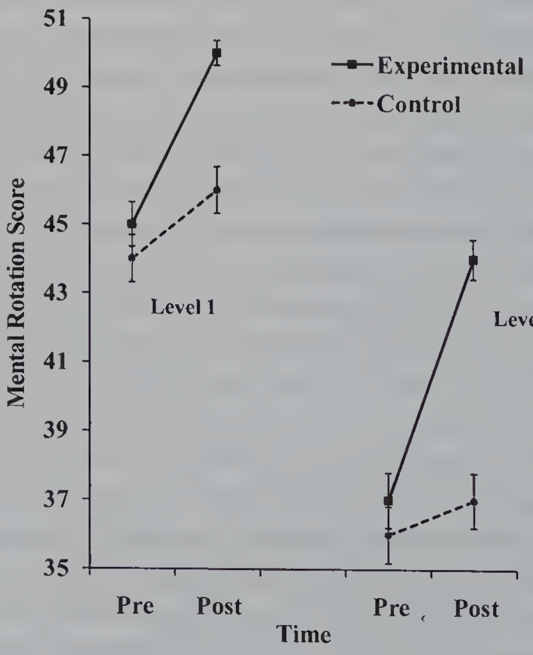

Figure 6. Pre- and postteaching performance on mental rotation in the experimental and control groups for each test level.

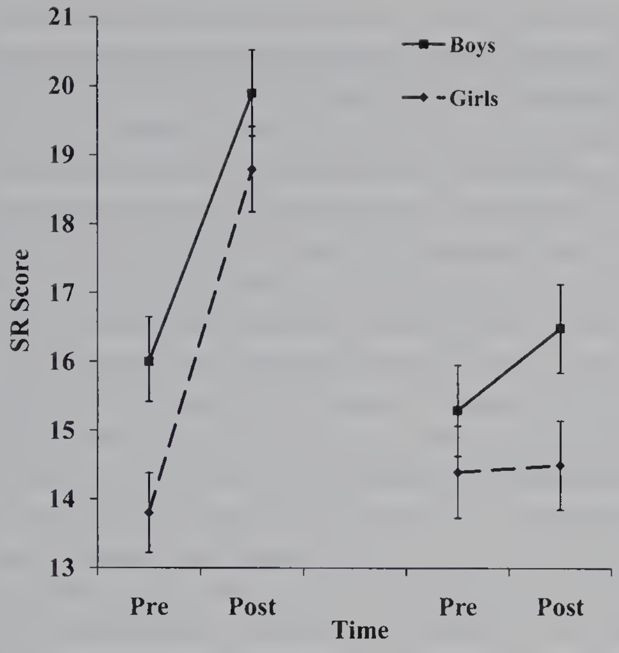

Figure 7. Pre- and postintervention Spatial Relations (SR) scores by treatment group and gender.

group, on the other hand, boys performed better than girls in both pre-, $t(1, 54) = 2.44$, $p < .01$, and postintervention, $t(1, 54) = 2.55$, $p < .01$, phases. Thus, the intervention moderated and even canceled out the initial gender differences. Furthermore, *in the postintervention phase the experimental girls performed significantly higher than the control boys*, $t(1, 56) = 2.68$, $p < .01$. The SR findings are very similar to those found for the WT and support out main hypothesis.

Effect-Size Analyses

In order to compare our findings with previous studies, we calculated the effect size of gender differences in the preintervention phase using Cohen's *d*. The results for gender, yielded an effect size of $d = .45$ ($r = .22$), $d = .69$ ($r = .32$), and $d = .60$ ($r = .28$) for the SR, WT1, and WT2, respectively. These effect sizes are very similar to the effect sizes found with older children and adults using spatial tasks like the Shepard Metzler mental rotation test (Voyer et al., 1995). It should be noted that the initial gender differences in our study are not likely to be attributed to general cognitive ability, as there were no gender differences on the WISC–R95 subscales of Vocabulary, $t(1, 114) = .64$, *ns*, and Concept Formation, $t(1, 114) = .30$, *ns*. Additional effect-size analyses were calculated for gender differences in the experimental and control groups before and after the intervention, using a composite score of WT (WT1 + WT2). The findings indicate that although in the experimental group the effect size decreased drastically from pre- (.71) to postintervention (.23), in the control group the effect size increased from pre- (.68) to postintervention (.73).

GLPS as a Moderating Factor Between Gender and Mental Rotation

The second objective of this study was to investigate whether the GLPS is a moderating factor that explains gender differences in mental rotation performance as well as the interactive effects of GLPS and task difficulty on mental rotation.

Prior to analyzing the effect of GLPS as a moderating factor of gender differences in mental rotation, we carried out two analyses to establish gender differences in GLPS. The first analysis was an ANOVA of Gender × Treatment (2 × 2) on GLPS. The ANOVA revealed a significant main effect of gender, $F(1, 112) = 25.76$, $p < .001$, $\eta^2 = .19$, indicating that boys were more global than were girls in their perceptual judgments, across treatment groups. Out of a possible total score of 16, the mean global choices selected were 10.14 ($SD = 2.15$) and 5.03 ($SD = 2.05$), for boys and girls, respectively.

The effect of the GLPS as a moderating variable was analyzed in a repeated measures MANCOVA of Gender × Treatment × Test Level × Degree of Rotation with GLPS as a covariate. The dependent variables were WT1 and WT2, which allowed the comparison of test levels and degrees of rotation. The findings revealed that (a) the gender main effect, which was significant in a previous MANOVA, $F(1, 112) = 12.80$, $p < .001$, $\eta_p^2 = .10$, was no longer significant in the current MANCOVA, $F(1, 111) = 1.75$, *ns*. Thus, once GLPS was included as a covariate, the gender main effect is not significant. (b) A significant interaction of GLPS × Degree of Rotation, $F(1, 111) = 5.08$, $p < .05$, $\eta^2 = .08$, indicates that the higher the degree of rotation, the higher is the contribution of a global orientation to mental rotation performance. As expected, the main effects of (c) test level, $F(1, 111) = 125.18$, $p < .001$, $\eta^2 = .53$; (d) degree of rotation, $F(1, 111) = 227.28$, $p < .001$, $\eta^2 = .81$; and (e) GLPS (covariate), $F(1, 111) = 31.51$, $p < .001$, $\eta^2 = .22$, were significant. These findings indicate that the higher the degree of rotation, test level, and the GLPS scores, the higher is the mental rotation score.

Further support for the relation between GLPS and mental rotation was indicated by correlation analysis. Pearson correlations between a combined preintervention WT score (WT1 + WT2) and GLPS score, showed positive significant correlations of .60 ($p < .001$) and .50 ($p < .001$) for the experimental and control groups, respectively. Similarly, the correlations between the GLPS and the initial SR scores were .30 ($p < .01$) and .28 ($p < .05$) for the experimental and control groups, respectively. These findings indicate that a global strategy was more efficient than a local strategy for solving mental rotation tasks.

Discussion

Data analysis of the pre- to postintervention scores showed clearly that the training program, focused on teaching of representation and transformation of spatial information, brought about a significant improvement in the spatial performance of young children, as well as a significant mitigation of the initial gap between boys and girls. The experimental group improved significantly more than the control group on both WT (Figure 4) and SR (Figure 7) tests. As the experimental and control groups showed high initial similarity on mental rotation scores, the observed improvement of the experimental group can be attributed mainly to the intervention effects. The slight improvement of the control group may indicate a self-practice effect caused by a repeated administration of the tasks. These findings differ from previous training studies, which indicate that the performance levels of males and females rise in parallel and maintain the gender gap (e.g., Baenninger & Newcombe, 1989; Levine et al., 1999).

Comparison of the pre- to postintervention improvement of boys and girls showed that girls' improvement in the experimental group was greater than that of boys and that the girls closed the initial gap. This finding was repeated in both the WT (Figure 4) and the SR (Figure 7) tests. Similar comparisons in the control group showed that the initial gender gap differences were not reduced from pre- to postintervention; on the WT, there were minor equal improvements among both boys and girls, and on the SR test, boys showed a slight improvement whereas girls showed no improvement. Moreover, in the postintervention phase, *girls in the experimental group showed higher performance than did boys in the control group; this improvement occurred on both tests*. Further support for the effectiveness of the intervention in reducing gender differences was evident in the effect-size findings. The effect size decreased sharply from pre- to postintervention in the experimental group but increased in the control group. A possible explanation for the uniqueness of our findings relates to the type of training given as well as to its intensity. It appears that self-training caused by repeated administration of the tasks, characterizing previous studies, was not alone sufficient to narrow the gap between boys and girls. As shown in previous studies (e.g., Marulis et al., 2007), males and females benefit equally from this type of self-training on spatial tasks. The findings of our experimental group revealed, on the other hand, that a relatively long-term *deliberated/instructive* training program based on teaching strategies for the transformation of visuospatial stimuli brought about substantial improvement in mental rotation of young children, particularly of girls who reached the same performance level as boys. The strategies focus on expanding working memory, perceiving spatial information in a global rather than analytic way, and flexibly conceptualizing spatial stimuli from different points of view. These findings are consistent with recent adult studies showing that females benefited more than males from active and guided training programs such as training with computer and video games, and that prior gender disparities in spatial ability, as measured by mental rotation tasks, were significantly reduced (Coluccia & Louse, 2004; Feng et al., 2007).

Support for our findings is found in Linn and Petersen's (1985) analysis of the processes that underlie the solution of mental rotation tasks. They suggested that a global-holistic or a Gestalt-like strategy is more effective than a part-by-part analytic approach. As the mental rotation tasks yield the largest and most robust gender differences, they raised the possibility that gender differences on these tasks are associated with the selection or efficient application of solution strategies. This argument is also supported by recent studies showing that boys tend more often than girls to adopt global-holistic strategy in processing visuospatial information since the early childhood years (e.g., Kramer et al., 1996; Lawton, Charleston, & Zieles, 1996; O'Laughlin & Brubaker, 1998).

Because mental rotation is considered to represent a high level of spatial cognition (Gardner, 1983) as well as the skill found to be most related to gender differences (Linn & Petersen, 1985; Voyer et al., 1995), our findings are of most importance. They suggest that early *deliberate/instructive* training programs might help to bridge the gender gap in spatial ability, whether the differences in ability are attributed to biological mechanisms or to environmental inputs. Moreover, our findings indicate that girls in the experimental group outperformed boys in the control group on both the SR and the WT tasks. These findings strengthen our claim that strategy-oriented intervention can overcome gender differences considered by many researchers to be biologically determined. Newcombe et al. (2002) noted that although the question of the origins that lead to the observed gender differences in spatial competence may be of scientific interest, *it is more important to determine whether intervention can reduce or eliminate them.* We would add that adequate intervention could reverse gender differences causing girls to perform higher than boys!

In the current research, first-grade boys showed higher initial performance than girls on a standardized SR test and even more on the WT, which was specifically developed to tap spatial skills involving mental rotation of young children. These initial gender differences are not likely due to intellectual ability, as boys and girls performed similarly on Vocabulary and Concept Formation subtests of the WISC–R or by SES level.

One of our main hypotheses was that processing strategies moderate and help to explain initial gender differences in mental rotation. By using Kimchi and Palmer's (1982) GLPS tasks, we first found that children who used a global-holistic strategy in their perceptual judgments were more likely to succeed in solving the mental rotation tasks, than children who used a local strategy: The GLPS scores were significantly and positively correlated with the SR and WT scores. The hypothesis is also strongly supported by two interrelated findings. The first is that once we introduced the GLPS variable as a covariate into the MANOVA (see previously mentioned MANOVA of Treatment × Gender × Time × Test Level × Degree of Rotation), the significant main effect of gender disappeared. The second is the finding showing that the GLPS score (introduced as a covariate) was significantly and positively related to the mental rotation scores. These findings support our assertion that a global-holistic strategy is more efficient than a local strategy in solving spatial tasks involving mental rotation.

Clinical observations of strategies used by boys and girls clearly show that boys used significantly more perceptual global judgments than girls did. Analysis of the GLPS scores indicated that boys tended to focus on the global shapes with more attention to the outer configurations, whereas girls tended to focus on the local elements in a more details-oriented fashion. This finding is consistent with Kramer et al. (1996), who used the same global–local paradigm with children between the ages of 4 and 12 years, and reported large gender differences with greater global bias in boys at all ages. These findings support our hypothesis that early gender differences in strategies used to process visuospatial information account for at least a portion of the gender differences in spatial performance as measured by mental rotation tasks. We would like to note that more evidence should be provided concerning the change in strategy usage from pre- to postintervention as well as the change in correlation patterns between mental rotation and processing strategies. Unfortunately, we did not gather information on the strategies used *during* testing; neither did we administer the GLPS test at the end of the intervention. In future research, we suggest use of the GLPS both before and after the intervention so that simultaneous comparisons can be carried out on mental rotation performance and processing strategies. We expect the intervention not only to affect both domains but also to observe a correlation between pre and postchanges in both domains. The findings showing that gender differences in mental rotation are moderated by differences in global–local strategies used to complement our expectations that a training program aimed at improving mental representation and transformation of visuospatial information would provide girls with opportunities to select and apply more efficient strategies for solving mental rotation tasks, leading to a reduction in gender differences.

In congruence with findings of meta-analytic studies (Linn & Petersen, 1985; Voyer et al., 1995), the magnitude of gender differences in the current study was influenced by task demands. Analysis of the interactive effects of treatment and task demands in WT revealed significant interactions of treatment with the degree of rotation (Figure 5) and test level (Figure 6). These interactions indicate that the higher the task difficulty, the higher was the impact of the intervention. On both variables, the experimental children showed significantly higher pre- to postintervention improvement on the difficult tasks than on easy tasks whereas the control group children showed consistent, slight and insignificant improvement.

Similar to the intervention effects on different levels of task difficulty, our findings indicate that the global strategy is more efficient in coping with tasks of high level than with low level of mental rotation. This was shown by the significant interaction of GLPS × Degree of Rotation and by the correlation analysis indicating higher correlations between WT and GLPS with increase in levels of rotation.

The origins that lead to the observed gender differences in strategies used for processing visuospatial information have not been clarified yet. On the one hand, evidence for biological mechanisms may derive from differences emerging by early childhood and remain relatively constant over the course of development (e.g., Kramer et al., 1996). On the other hand, these differences might be attributed to different experiences that are relevant to acquisition, selection, and application of solution strategies (Halpern, 2004; Linn & Petersen, 1985). Longitudinal and cross-sectional research showing parallel developmental trajectories of mental rotation and global–local strategies might help to establish the relation between the two domains.

In conclusion, given the fact that superior spatial skills are important in mathematical and scientific thinking (e.g., Clements & Battista, 1992; Gardner, 1983; Wheatley, 1990, 1991, 1996, 1997; Wheatley & Reynolds, 1999), it is crucial to implement intervention programs aimed at improving spatial skills and help to bridge the gap between males and females in these areas. In our study, mental rotation was found as a malleable domain that can be acquired through training. The findings indicate also that mental rotation is intimately related to global–local perception and that holistic strategies can help the individual in representing and transforming perceptual stimuli and directly affect mental rotation skills.

In view of the importance of spatial ability in many scientific domains and in view of the current results in supporting intervention for developing spatial skills, we recommend, together with others (e.g., Vasta et al., 1996; Webb et al., 2007), that more emphasis is needed to nurture such skills within the school curriculum. Training should include enhancing the processing strategies of visuospatial stimuli using computer technology (e.g., virtual reality) and targeted instructional approaches. Training should start as early as possible to prevent gender differences and to provide equal opportunities for girls to excel in spatial abilities that are required for success in scientific domains. Because girls have been shown to have fewer out-of-school spatial experiences than boys, many girls may never tap their potential to think spatially, unless spatial thinking is specifically introduced into the school curriculum. Nevertheless, further research is necessary to identify specific experiences that promote the development of spatial skills of young children.

Interracial and Intraracial Contact, School-Level Diversity, and Change in Racial Identity Status Among African American Adolescents

Tiffany Yip
Fordham University

Eleanor K. Seaton
University of North Carolina, Chapel Hill

Robert M. Sellers
University of Michigan

Among 224 African American adolescents (mean age = 14), the associations between interracial and intraracial contact and school-level diversity on changes in racial identity over a 3-year period were examined. Youths were determined to be diffused, foreclosed, moratorium, or achieved, and change or stability in identity status was examined. Contact with Black students, Black friends, and White friends predicted change in identity status. Furthermore, in racially diverse schools, having more Black friends was associated with identity stability. Students reporting low contact with Black students in racially diverse schools were more likely to report identity change if they had few Black friends. In students reporting high contact with Blacks in predominantly White schools, their identity was less likely to change for students with fewer White friends.

Intergroup contact theory suggests that, under certain conditions, the more intergroup contact individuals have, the more likely they are to feel positive toward out-group members (Pettigrew, 1998). Indeed, research has shown that positive interactions with different-race individuals have been associated with outcomes such as reduction in prejudice (Molina & Wittig, 2006), increases in a sense of common identity (Nier et al., 2001), and personal closeness (Tropp, 2007). In a meta-analytic review of studies that have examined the contact hypothesis, Pettigrew and Tropp (2006) reported that intergroup contact has a positive impact on reducing prejudice for members of the general outgroup and not just specific members with whom an individual has had interactions. However, as Pettigrew (1998) writes, "optimal intergroup contact provides insight about ingroups as well as outgroups" (p. 72). Indeed, research suggests that in-group and out-group contact influences the development of racial identity (Alba & Nee, 2003; Portes & Rumbaut, 2001). The current study will address two gaps in the current literature on the effects of contact on adolescent development. First, the study will consider the influences of both intergroup and intragroup peer contact and friendships on changes in youth's feelings about their own racial identity over time. Finally, this study will consider the opportunities that youth have for interracial and intraracial contact and friendships by examining how contact interacts with school-level diversity to influence racial identity changes.

Racial Identity Development

Many scholars have discussed the importance of identity exploration and construction during adolescence (Erikson, 1968; Marcia, 1980; Phinney, 1993). Indeed, identity status models outline how the combination of identity exploration and commitment change as adolescents learn more about their racial group. Specifically, Marcia (1966) and Phinney (1992) offer a model of identity development where adolescents can be in one of four statuses: neither explored nor committed to their identity (diffused), committed to an identity without exploring (foreclosed), explored but have not committed (moratorium), or have both explored and committed to an identity (achieved). Inherent

in this model is a pattern of linear progression from less to more advanced stages. Recently, empirical work has lent some support to this theory finding that adolescents were more likely to report being in the less advanced statuses when compared with older adults (Yip, Seaton, & Sellers, 2006). Other research finds that even from one year to the next, adolescents report moving from one identity status to another (Seaton, Scottham, & Sellers, 2006). Thus, racial identity appears to be changing for minority youth during the adolescent period, but the empirical literature is less clear about antecedents to change in racial identity status.

Intergroup Contact and Racial Identity

There are many possibilities for what might precede changes in identity. One such consideration is social interactions with other-race peers. In one of the few studies examining the association between racial identity and intergroup contact, Lee, Noh, Yoo, and Doh (2007) found that among Koreans living in China, those who reported more social interactions with Chinese reported lower levels of ethnic identity when discrimination was frequent. In a study of African, Asian, and European American adolescents, Hamm (2000) found that only for European Americans did having cross-race friendships have an association with ethnic identity. In particular, it was observed that having a cross-race friendship was associated with higher scores on importance and positive regard for one's ethnicity. In a study of Latino adolescents, attending a predominantly non-Latino school was associated with stronger ethnic identity (Umana-Taylor, 2004). Together, these studies suggest intergroup contact may have important implications for identity development. However, as none of these studies employed longitudinal data, the nature of the relation between contact and racial identity is unclear.

Intragroup Contact and Racial Identity

Although the contact hypothesis focuses primarily on the effects of intergroup contact, research has also examined the very important influence of intragroup interactions for youth development. For example, in a study of African American adolescents, Rowley, Burchinal, Roberts, and Zeisel (2008) found that same-race friendships were associated with increased reports of racial discrimination. Although same-race friends were not linked to racial identity explicitly in that study, recent research suggests that discrimination is a form of social interaction that may then lead to the exploration of and commitment to one's identity (Seaton, Yip, & Sellers, 2009). Specifically, theory suggests that experiences of racial discrimination may serve as encounters that cause individuals to rethink the role of race in their lives, a process that can occur anywhere in the developmental life span (Cross & Fhagen-Smith, 2001). In research that considered ethnic identity as an outcome, researchers found that having a stronger sense of ethnic identification was associated with more in-group peer interaction (Phinney, Romero, Nava, & Huang, 2001). In retrospective research on Black college students who are attending predominantly White high schools, it was observed that having positive same-race peer relationships was associated with more resolution in racial identity formation (Tatum, 2004). Therefore, it seems that having more same-race friends may be associated with changes in racial identity status over time. Taken together, the current empirical literature suggests that both intergroup and intragroup contact could be related to changes in racial identity.

School Diversity

Implicitly, intergroup contact theory suggests that individuals should have opportunity to interact with out-group members in everyday contexts. Indeed, scholars have discussed the importance of opportunity for contact in the context of macro-level variables such as diversity, in their discussion of intergroup contact theory (de Souza Briggs, 2007; Pettigrew, 2006). As the primary context in which adolescents have contact with peers is school, this study considers school-level diversity as an indicator of the opportunities that youths have to interact with same- and different-race peers. Schools that are characterized by high diversity afford youths increased opportunity to interact with same- *and* different-race peers. Schools with low diversity, however, may only offer youths the opportunity to interact with same- *or* different-race peers, but not both. Therefore, the current study considers school-level diversity as an important third variable to consider in examining the association between contact and changes in racial identity.

Furthermore, even with the opportunity to interact with same- and different-race peers, adolescents may not actually interact with them. For one, there may be institutional barriers; for example, classes may be organized in a manner that is not conducive to interactions between students in different academic tracks (Kubitschek & Hallinan, 1998; Mickelson &

Heath, 1999). Specifically, research suggests that academic tracks often differ by race (Schwarzwald & Cohen, 1982). Beyond academic divisions, in social interactions, it has also been observed that youths may self-segregate and befriend only same-race peers (Tatum, 1997). For example, a study of Dutch adolescents found that despite attending diverse schools where at least half of the students were not Dutch, 16% of the Dutch students reported having no contact with non-Dutch peers (Masson & Verkuyten, 1993). Outside of school, where students presumably have more choice about whether or not to engage in intergroup interactions, 45% of students reported little or no cross-ethnic interactions. In this same study, students reporting a more positive attitude about their racial group also reported less intergroup contact. In a study of Black and White fourth grade students, researchers found that students attending an integrated school were much more likely to mention race and ethnicity in discussions about self-concept than children attending predominantly Black or White schools (Dutton, Singer, & Devlin, 1998). As such, it seems important to consider not only youths' opportunities to interact with same- and different-race peers, but also behavioral indicators of whether or not youth actually make friends with same- and different-race peers.

Friendships

Therefore, another approach to evaluating the contact hypothesis (Pettigrew, 2007) includes research in the area of cross-race friendships. As an operationalization of the contact hypothesis, studies of cross-race friendships have lent support to the basic tenets of the theory. For example, research examining school-level racial diversity on friendship choices among high school students finds that the higher the proportion of same-race peers in a student's school, the more likely he or she will be to have same-race friends (Kao & Joyner, 2006; Kao & Vaquera, 2006). Similarly, other research suggests that cross-race friendships are more likely in more racially diverse schools (Quillian & Campbell, 2003). Patterns for ethnicity are analogous, such that attending a school with more same-ethnicity peers also makes it more likely that students will report having more same-ethnicity friends (Kao & Joyner, 2006).

From a probabilistic point of view, it seems logical that the more opportunity one has to form cross-race friendships, the more likely the friendships will occur. However, research suggests that actual behavior patterns are less predictable. Research on Black and White school children has found that students in integrated and predominantly White schools were more likely to report having cross-race friendships (Dutton et al., 1998). In a study of Black and White students attending an integrated junior high school, most students reported having a close other-race friend; however, only 28% of the sample reported having interactions with other-race friends off campus (DuBois & Hirsch, 1990). At the same time, research on adolescents has observed when one's group represents a small minority in an otherwise homogenous school, the probability of same-race friendship increases (Quillian & Campbell, 2003). In a study with adults, using multilevel models that estimated the probability of establishing cross-race friendships given the relative proportions of different ethnic groups in one's community, de Souza Briggs (2007) analyzed the friendship patterns of over 20,000 adults in the United States. These data suggested that the single greatest predictor of whether or not a European American adult reported having a cross-race friendship was the region of the country in which the individual resided. Even so, the actual rates of cross-race friendships fall short of the predicted probability (as estimated by a random choice model given the racial distribution of one's local area) for all ethnic groups (de Souza Briggs, 2007). In other words, even though living in a more diverse area provided increased opportunity to form cross-race friendships, individual differences still account for whether or not people actually formed cross-race friendships.

The current study will examine the prospective effects of intergroup and intragroup contact and friendships on changes in racial identity status in a 3-year longitudinal sample of African American adolescents living in a predominantly White Midwestern town. Interracial and intraracial contact is operationalized in two ways: (a) as students' reports of the proportion of other Black youth in their classes and clubs and (b) as friendships, the number of close White and close Black friends each student reports. We hypothesize that interracial contact and intraracial contact may or may not have independent effects on whether youths' racial identities change or remain stable. Instead, we do expect that contact and context will interact to determine whether there are changes in racial identity over time. For the purposes of this study, context is operationalized as diversity using school-level information about the racial composition of each student's school.

Method

Participants

These data are drawn from a 3-year longitudinal study of racial identity development, racial socialization, and psychological adjustment among African American adolescents residing in the Midwest. About 15% of residents in the school district reported being African American, whereas 54% reported being of European American descent. There were more females than males in the study (60%) and the median family income was reported by parents to be between $40,000 and $49,000. Although the median income for African American families in this community is greater than the national average range ($30,000–$39,000), there is variation for the participants' families.

Students began the study either in the 7th, 8th, 9th, or 10th grade (mean age = 13.83 years old, $SD = 1.11$), and were administered surveys once a year for 3 years. Students attended 10 schools in the same school district (6 middle and 4 high schools). At all three time points, data were collected from both an adolescent and his or her primary caregiver. Five hundred and forty-six students completed surveys during the 1st year of the study. In Year 2, 379 of those students returned. A total of 260 adolescents completed all three time points. With the exception of one school, all schools were predominantly White; therefore, for ease and consistency of interpretation, the predominantly Black school was omitted from the analyses presented here. As such, the current study includes the 224 adolescents who had complete data at all three time points. To address whether the data were missing at random, chi-square and analyses of variance (ANOVAs) compared adolescents with complete data across the three time points with adolescents who were omitted from the current study for not having data at all three times points. Examining gender and racial identity variables, there were no significant differences between adolescents who completed all three waves of the study compared with those who only completed one or two waves: gender, $\chi^2(2) = 1.08$, *ns*; exploration, $F(2, 543) = 0.28$, *ns*; and commitment, $F(2, 543) = 2.49$, *ns*.

Procedure

The specific procedures for the longitudinal study have been described elsewhere (Seaton et al., 2009). All adolescents identified as African American by the school district were contacted by phone or mail to participate in the study. At each survey administration, adolescents were asked to sign assent forms. Adolescents completed pencil-and-paper surveys in small groups after school and sessions lasted between 45 and 75 min. Students were compensated with $30, $40, and $50 gift certificates to the local mall for each year of the study, respectively.

Measures

Racial identity. The Multigroup Ethnic Identity Measure (MEIM) comprised four subscales: affirmation and belonging, identity achievement, racial behaviors, and other-group orientation (Phinney, 1992). The identity achievement subscale, which measured exploration and commitment, was used in the present study. The scale consists of items with responses ranging from 1 (*strongly disagree*) to 4 (*strongly agree*), such that higher scores represent strong endorsement of their respective constructs. Previous research using the MEIM reported a two-factor solution consisting of affirmation and belonging (affirmation, belonging, and commitment items) and identity search (exploration and ethnic behavior items; Phinney, 1992; Roberts et al., 1999). However, previous work has not exclusively focused on the achievement subscale, which measures exploration and commitment (Phinney, 1992). As the goal of the present study was to create the identity statuses from exploration and commitment levels, it was appropriate to separate the achievement subscale into exploration and commitment dimensions.

A confirmatory factor analysis was conducted to discern whether the achievement subscale consisted of two oblique latent factors with exploration and commitment items at all three time periods. The results indicate an average fit to the data for Time 1 ($\chi^2 = 25.19$, $df = 8$, $\chi^2/df = 3.15$, Tucker-Lewis index [TLI] = .82, comparative fit index [CFI] = .93, root mean square error of approximation [RMSEA] = .10), Time 2 ($\chi^2 = 18.49$, $df = 8$, $\chi^2/df = 2.31$, TLI = .91, CFI = .96, RMSEA = .08), and Time 3 ($\chi^2 = 47.99$, $df = 8$, $\chi^2/df = 5.99$, TLI = .62, CFI = .86, RMSEA = .15), providing an empirical justification for separating the achievement subscale of the MEIM into exploration and commitment indices.

As analyses were conducted over a 3-year time frame to measure change in racial identity, it was important to establish that observed change is due to differences in youths' reports and not measurement variance. In order to examine invariance, differences in the chi-square statistic were examined over time for the unconstrained model, the constrained measurement weights model, and the constrained measurement intercepts model. Differences in the chi-square statistic involve comparing the change in χ^2 with a critical ratio. The test comparing the unconstrained model with the constrained measurement weights model was not significant, $\Delta\chi^2 = 7.05$, with the critical ratio equivalent to 15.51. The test comparing the unconstrained model with the constrained measurement intercepts model was not significant, $\Delta\chi^2 = 28.75$, with the critical ratio equivalent to 31.41. Thus, the results suggest that the confirmatory factor analytic models are invariant across time.

The resulting exploration subscale consists of four items rated on a 4-point Likert scale, which range from strongly disagree to strongly agree (Time 1: $M = 2.87$, $SD = 0.63$; Time 2: $M = 2.82$, $SD = 0.57$, Time 3: $M = 2.79$, $SD = 0.64$), and a sample item includes ''I think a lot about what being Black means for my life'' (Time 1: $\alpha = .66$; Time 2: $\alpha = .63$; Time: 3 $\alpha = .64$). The commitment subscale has two items rated on a 4-point scale (Time 1: $M = 3.09$, $SD = 0.70$; Time 2: $M = 3.02$, $SD = 0.72$, Time 3: $M = 2.98$, $SD = 0.72$) and a sample item includes ''I understand pretty well what being Black means to me'' (Time 1: $\alpha = .68$; Time 2: $\alpha = .69$; Time 3: $\alpha = .71$).

Because the Cronbach's alphas for the exploration and commitment variables included significantly fewer items than the full-item MEIM, the Spearman–Brown formula was used to calculate the estimated Cronbach's alphas if the subscales included 12 items (equivalent to the full-item MEIM). The estimated Cronbach's alphas are: exploration (Time 1: $\alpha = .83$; Time 2: $\alpha = .83$; Time 3: $\alpha = .85$) and commitment (Time 1: $\alpha = .83$; Time 2: $\alpha = .84$; Time 3: $\alpha = .82$). These coefficients are comparable with existing research employing the 12-item MEIM; for example, $\alpha = .82$ (Roberts et al., 1999), $\alpha = .75$ (McMahon & Watts, 2002), and $\alpha = .82$ (Bracey, Bamaca, & Umana-Taylor, 2004). Scores for each subscale were developed by averaging across the items, and higher scores are indicative of high levels of exploration or commitment.

Interracial contact. Two questions were asked: ''Which of the following best describes the racial makeup of the students in most of your classes?'' and ''Which of the following best describes the racial makeup of the people in most of the clubs, teams, or other organizations you are currently involved in?'' Responses included 1 (*almost all White students*), 2 (*more White than Black students*), 3 (*same number of Black and White students*), 4 (*more Black than White students*), and 5 (*almost all Black students*). These two items were averaged together to estimate contact ($M = 2.37$, $SD = 0.92$). Higher scores indicate more contact with same-race, Black youths.

Friendships. As another measure of contact (interracial and intraracial), we assessed youths' reported friendships. ''How many of your close friends are Black?'' assessed intraracial close friendships. An analogous question, ''How many of your close friends are White?'' assessed interracial close friendships. Responses included 1 (*none*), 2 (*a few*), 3 (*half*), 4 (*most*), and 5 (*all*). To keep interracial and interracial friendships distinct, these items were kept separate and higher scores represent more close friendships with Black and White students ($M = 3.07$, $SD = 0.78$; $M = 2.60$, $SD = 0.75$, respectively).

School diversity index. The racial diversity of each school was obtained with archival data from the school district. The racial diversity of each student's school was computed based on information about the percentage of African American, Asian, White, Hispanic, Middle Eastern, Native American, multiethnic, and other students. Employing methods described in Juvonen, Nishina, and Graham (2006), the racial diversity of each student's school was computed based on information about the percentage of students in each racial group. Using information about the number of different racial/ethnic groups (g) and the proportion of individuals (p) who are members of each group (i), the index (D_C) provides an estimate of the relative probability that two randomly selected students are from different racial/ethnic groups:

$$D_C = 1 - \sum_{i-1}^{g} p_i^2.$$

Higher scores (range from 0 to 1) indicate more diversity (i.e., presence of other racial minorities), whereas lower scores indicate less diversity (i.e., predominantly White) and indicators were computed for all three time points (Time 1: $M = .57$, $SD = 0.09$; Time 2: $M = .57$, $SD = 0.08$; Time 3: $M = .58$, $SD = 0.08$).

Results

Correlations between the primary study variables are presented in Table 1. Among the Time 1 variables, reporting having more contact with Black students in classes and clubs was positively associated with reporting having more close Black friends, fewer close White friends, and higher

school diversity. Reporting more close Black friends was associated with having fewer close White friends. Similar patterns were observed among the Time 2 variables. Among the Time 3 variables, one difference is noted: The composition of classes and clubs is no longer associated with the school diversity index.

Examining the correlations across adjacent time points, Time 1 composition of classes and clubs is positively correlated with reports at Time 2. Time 1 composition of classes and clubs is also positively associated with having more close Black friends but negatively associated with having more close White friends. Reporting more close Black friends at Time 1 was positively associated with having more contact with Black students, more close Black friends, and fewer White close friends at Time 2. The number of close White friends reported at Time 1 was negatively associated with close Black friends at Time 2, but positively associated with close White friends at Time 2. School diversity at Time 1 was associated with more contact with Blacks; more close Black friends, and school diversity at Time 2. However, school diversity at Time 1 was negatively associated with close White friends at Time 2.

Examination of the Time 2 and Time 3 adjacent time points suggest that there was stability in composition of classes and clubs. There was also a positive association between composition and close Black friends, but a negative association with close White friends. Consistent with previous time points, there was a negative association between reports of close White friends and close Black friends between Time 2 and Time 3, but stability in reports of the same racial groups over time. Finally, stability was observed for reports of school diversity at Time 2 and Time 3. Looking over a 2-year period, having more Black students in classes and clubs at Time 1 was positively associated with the same variable at Time 3. And as with previous time points, Time 1 contact was positively associated with having more close Black friends and negatively associated with having close White friends. Having many close Black friends at Time 1 was associated with having many close Black friends at Time 3, fewer close White friends, and reporting more Blacks in classes and clubs. Again, stability was observed for not only having close White friends from Time 1 to Time 3, but also associated with having fewer close Black friends and reporting fewer Black students in classes and clubs. The school diversity index at Time 1 was positively associated with having more close Black friends at Time 3, as well as school diversity at Time 3. School diversity at Time 1 was negatively associated with reports of close White friends at Time 3. As the school diversity index over the three time points was so highly correlated, a mean was computed of the three indices and this index was used for the analyses that follow.

Racial Identity Statuses

Before examining change in racial identity statuses, we first determined which racial identity clusters were present in the data. Consistent with racial identity status theory and with previous research (Yip et al., 2006), we expected to find four identity statuses that reflect the diffused, foreclosed, moratorium, and achieved profiles. *K* means cluster analyses were utilized to identify homogenous racial identity statuses among standardized exploration and commitment variables. *K* means analyses are the most appropriate technique when there is a theoretical rationale for a specific number of clusters (Hair & Black, 2000). The specific statistical techniques used to create the four identity status groups have been described elsewhere (Yip et al., 2006). Consistent with Phinney's (1989) identity formation model, the data suggested the presence of four distinct identity profiles. The first profile had significantly lower scores on the exploration and commitment subscales and was classified as diffuse (Time 1: $n = 21$; Time 2: $n = 31$; Time 3: $n = 36$). A second cluster reporting lower scores on the exploration subscale and higher scores on the commitment subscale was classified as foreclosed (Time 1: $n = 48$; Time 2: $n = 55$; Time 3: $n = 28$). A third cluster fits the description for moratorium, with higher scores on the exploration subscale and lower scores on the commitment subscale (Time 1: $n = 65$; Time 2: $n = 74$; Time 3: $n = 80$). The final cluster was classified as achieved, with higher scores on both the exploration and commitment subscales (Time 1: $n = 77$; Time 2: $n = 51$; Time 3: $n = 67$).

Interracial/Intraracial Contact and School Diversity

The racial identity status variable assessed whether individuals changed over time. Individuals who remained in the same status over time were labeled as *constant*, whereas individuals who changed identity status groups over time were labeled as *change*. Employing these coding methods, we observed that between Time 1 and Time 2, 42% of the sample reported no change in their racial identity status whereas the remaining 58% reported a change in their identity status. Between Time 2 and Time 3, 36% of the sample reported remaining in the same identity status whereas 64% did not. Finally, over the 2-year period between Time 1 and Time 3, 38% of students reported staying in the same identity status whereas 62% moving from one status to another.

The next step was to examine how interracial and intraracial contact prospectively predicted the observed changes in identity status. As such, binomial logistic regression analyses were conducted where identity change from Time 1 to Time 2 was coded as 1, and identity stability from Time 1 to Time 2 was coded as 0. Student age and gender were included as covariates. School diversity (mean of Time 1, 2, 3), number of close White friends (Time 1), number of close Black friends (Time 1), contact with Black students in classrooms and clubs (Time 1), the three possible interactions of school diversity with each of the three other independent variables, and the two possible interactions between school diversity, contact, and number of close Black and White friends were included as predictors (Table 2). A main effect of contact with Blacks in classrooms and clubs was observed such that more contact was associated with an increased likelihood of change in racial identity status. In addition, a three-way interaction between contact, diversity, and number of close Black friends was found, which is illustrated jointly in Figures 1 and 2. To graph the three-way interaction, a median split was computed for contact with Black students (Figure 1: low contact with Blacks; Figure 2: high contact with Blacks). Among students who reported having low contact with Black students (Figure 1), those with few close Black friends who reported attending schools with higher diversity (i.e., presence of other minorities) reported being more likely to change their identity status from Time 1 to Time 2. On the other hand, among students who reported having high contact with Black students

(Figure 2), school diversity and number of close Black friends had no association with the probability of identity change over time.

Examining the same relationships to predict change in racial identity from Time 2 to Time 3, there was evidence of a two-way interaction between school diversity and number of close Black friends (Table 3). As illustrated in Figure 3, as students reported an increase in number of close Black friends, students in low diversity schools (i.e., predominantly White) reported being more likely to report a change in identity status from Time 2 to Time 3. For students attending high diversity schools (i.e., presence of other minorities), however, it seems that reporting more close Black friends was associated with a decreased likelihood of change in identity status.

Analyses were also conducted examining change during the 2-year period between Time 1 and Time 3, and unlike the previous set of analyses, an effect was observed for number of close White friends (Table 4). Namely, there was a main effect of

number of close White friends where having more White friends was associated with an increased probability of identity change. As well, there was a main effect of having close Black friends associated with an increased likelihood of identity change. Finally, there was also evidence for a three-way interaction between contact with Black students, school diversity, and number of close White friends. To depict this interaction, the sample was divided using a median split of contact with Black students (Figures 4 and 5). As illustrated in Figure 4, students who reported low contact with Black students were less likely to report a change in their identity status if they attended low diversity schools (i.e., predominantly White) and reported having many close White friends. Alternatively, among students reporting high contact with Black students (Figure 5), attending a predominantly White school was associated with a decreased probability of identity change for adolescents reporting having few close White friends.

Discussion

The current study explored how contact with Black students in classes and clubs, close friendships with Black and White students, and school-level

diversity independently and jointly predict whether African American adolescents will report change or stability in their racial identity status over 1- and 2-year periods. The data suggested that there were independent effects of contact with Black peers, close White friends, and close Black friends. Interestingly, however, school-level diversity did not appear to have a main effect on the probability of change or stability in racial identity status. Instead, school diversity was observed to have a joint influence with close friendships and contact in classes and clubs. These results point to the active role that youths play in their own identity development. That is, the school setting does not shape racial identity development from a top-down approach; rather, the adolescent creates his or her developmental context through choices like one's close friendship network. To parallel the analyses, the results are discussed in the same order in which they were analyzed: first examining change between adjacent time points (i.e., T1 to T2, T2 to T3), then examining change over a 2-year period (i.e., T1 to T3).

Turning first to the change between T1 and T2, the results indicate a main effect of increased contact with Blacks in classrooms and clubs as linked to an increased likelihood of changing racial identity status among African American youth. This finding is consistent with other research indicating that racial identity was strengthened in the presence of same-race peers. For example, more in-group peer interactions were associated with a stronger sense of ethnic identification among diverse youth (Phinney, Horenczyk, Liebkind, & Vedder, 2001) and same-race peer relationships were associated with resolutions in racial identity formation among African American college students (Tatum, 2004). The present findings and past research suggest that increased contact with same-race peers is linked to changes in racial identity status over time. Although, in the current study, it is unknown if the nature of this change is progression or regression (as outlined in the identity status model; Marcia, 1966; Phinney, 1992), change is occurring under the influence of Black peers suggesting that same-race peers have an important influence on racial identity development.

In addition to this main effect, contact with Blacks in classes and clubs also appeared to interact with school diversity and number of close Black friends to predict change or stability in racial identity between the 1st and 2nd years of the study. Specifically, African American youth with few close Black friends in high diversity settings were more likely to change their racial identity status from Time 1 to Time 2. Recall that low-diversity settings are characterized as predominantly White schools whereas high-diversity settings offer the presence of both same and different race peers. We suggest that this finding indicates a mismatch between the adolescent's choice of friends and what the context allows with respect to opportunities for forming friendships. As suggested by the correlations between close Black and White friends, it seems that youths with few Black friends may have more White friends, but the increased numbers of Blacks in classes and clubs affords new opportunities for racial encounters. Nigresence theory posits that racial encounters result in individuals reevaluating the role that race plays in their lives, which results in an advanced and nuanced racial identity for African Americans (Cross & Fhagen-Smith, 2001). Nigresence theory suggests that racial encounters may be negative (e.g., racially discriminatory experiences) or positive (e.g., making the soccer team); therefore, youths with few Black friends may be experiencing positive encounters as they come into increased contact with their African American peers. These encounters may be more probable in high-diversity settings given the increased numbers of other African American youth, and they may result in increased exploration or commitment, which would be coded as a change in racial identity status in the current study.

Turning to the analyses examining predictors of the change from T2 to T3, the data indicate interactive effects between school diversity and having more close Black friends. Specifically, in high-diversity settings, youths who reported having many close Black friends also reported that their racial identity status was less likely to change. The findings suggest that intraracial friendships have differential influences on racial identity development depending on the level of diversity in the setting. One explanation for this finding is that low-diversity settings increase the likelihood of negative interactions (i.e., discriminatory treatment due to minority status), which may be linked to racial identity changes. Previous research indicates that greater school diversity was related to less positive perceptions of the general school climate (Benner, Graham, & Mistry, 2008) given that discrimination is believed to be maximized in evenly mixed racial contexts (Sigelman, Bledsoe, Welch, & Combs, 1996). Additional research indicates that perceptions of racially discriminatory acts by peers were associated with increased identity exploration levels over time among African American youth (Pahl & Way, 2006). Thus, low diversity levels may be associated with more perceptions of discrimination among African American youth, and these perceptions of racial discrimination may be influencing the increased likelihood of changing racial identity status groups. A second explanation is the quality of contact that African American youth have with Black and White friends. Diverse settings afford Black youth more opportunities to have White friends, but previous research suggests that ethnic minorities had less positive interactions with White friends than with friends of their same racial background (Shelton & Richeson, 2006). Yet, African American children who had more contact with Black friends considered the contact to be positive in that it helped prepare them for discriminatory treatment (Rowley et al., 2008). Thus, the nature of the interactions is distinct depending on the race of the friends and research suggests that less positive contact increases with more White friends. As such, these interactions may influence the degree to which African American youth change their racial identity status groups.

Finally, examining change over a 2-year period from T1 to T3, the data suggested an interaction between context, contact with Black students, and close friendships with White students. It appears that being in a predominantly White setting is an important factor for racial identity change when African American youths report having a lot of White friends but little contact with Blacks in their classes and clubs. Similarly, a predominantly White setting matters when youths have few close White friends and a lot of contact with Blacks in their classes and clubs. In both groups, youths are in predominantly White settings, but one group associates with a lot of White friends whereas the other group does not, and there is a decreased likelihood of racial identity change in both scenarios. One explanation is related to a tenet of the contact hypothesis, which posits that more intergroup contact results in more attention toward out-group members (Pettigrew, 1998). The nature of the predominantly White setting may result in increased awareness and attention to interactions with White out-group as opposed to Black in-group members. Hence, this focus may decrease the probability of change in the racial identity status groups among African American youth, as exploration and commitment related to being African American are minimized. The present findings are contrary to previous research conducted with White (Hamm, 2000) and Latino youths (Umana-Taylor, 2004), showing that cross-race friendships were influential for ethnic identity. In the present sample, students reported that about "half" of their friends were of each group on both the close Black friend and close White friend variable. Therefore, it seems as though most of the students in this sample did have both in-group and out-group friendships regardless of the diversity of the school. Despite this similarity, it seems that only close friendships with same-race peers interacted with school diversity to influence changes in youths' racial identity over time. This may be true because this study was conducted in a predominantly White town, so the significance and meaning of close Black friends was more influential for changes in racial identity, a finding consistent with prior research (Phinney, Romero, et al., 2001; Tatum, 2004).

Although the current study offers a more nuanced and detailed examination of the relations between contact, context, and identity change, there are a few limitations that require consideration. Although cluster analysis provides a valuable method for classifying individuals, the technique is sample dependent. An additional limitation concerns the lack of assessment for previous development in that cluster analysis does not account for previous exploration or commitment levels. Another consideration is that the current study only examined how school-based peer interactions and diversity influence racial identity outcomes and research suggests that only 28% of youths who report out-group friends in school also report having out-group friends outside of school (DuBois & Hirsch, 1990). Therefore, it would seem important for future research to consider interracial and interracial interactions that occur outside of the school context. In addition, the time period for change is unclear given that the data were collected once a year. Despite the fact that the observed changes in identity status at 1- and 2-year intervals are consistent with developmental theories suggesting adolescence is an important time for identity exploration and construction (Erikson, 1968), data collected at smaller intervals might suggest more stability or change. Similarly, data collected during smaller time intervals might provide more information about how antecedents (i.e., school diversity) are related to subsequent changes in identity status. It should also be noted that the sample size was too small to allow for more detailed analyses to identify subgroups of identity change trajectories (e.g., regressing from achieved to foreclosed vs. regressing from achieved to moratorium). For example, it is plausible that the interaction of school diversity and Black friends may be associated with specific trajectories. It is also important for future research to consider the content and quality of interracial and intraracial interactions and how these dimensions contribute to youths' thoughts and feelings about their racial group membership. Finally, the current study only examines the racial dimension of adolescents' identity development and does not capture the possibility that although adolescents may not be changing in their levels of commitment and exploration of their *racial* identity, they could be changing in terms of developing a bicultural or multicultural perspective.

Nevertheless, the current study represents an important and unique contribution to the racial identity development literature by assessing intergroup and intragroup contact and school diversity as antecedents of change. Although the contact hypothesis posits that contact will have a positive impact on reducing prejudice and bias toward out-group members (Pettigrew & Tropp, 2006), the results suggest that intergroup contact has important implications for racial identity development among African American youths. Specifically, school diversity and having Black friends influence whether African American youths change racial identity status groups or remain stable across time. As racial identity has been shown to be an important construct for African American and minority youths, this study advances our understanding of key antecedents for this integral developmental process.

Do Adolescents and Parents Reconstruct Memories About Their Conflict as a Function of Adolescent Attachment?

Matthew J. Dykas
State University of New York at Oswego

Susan S. Woodhouse

Katherine B. Ehrlich and Jude Cassidy
University of Maryland

This study examined whether 17-year-old adolescents (n = 189) and their parents reconstructed their memory for an adolescent–parent laboratory conflict over a 6-week period as a function of adolescent attachment organization. It also compared participants' perceptions of conflict over time to observational ratings of the conflict to further characterize the nature of the attachment-related memory biases that emerged. Secure adolescents reconstructed interactions with each parent more favorably over time, whereas insecure adolescents showed less favorable reconstructive memory. Likewise, mothers of secure girls reconstructed conflicts more favorably over time, whereas mothers of insecure boys showed less favorable reconstructive memory. Participant ratings were associated with observational ratings in theoretically consistent ways. Contrary to expectations, fathers showed no attachment-related memory biases.

Developmental researchers have shown considerable interest in understanding the nature of adolescent–parent conflict. The causes of adolescent–parent conflict, for example, have been relatively well studied, and data indicate that such conflict stems from both normative changes within the child–parent relationship (e.g., puberty-related biological changes, increasing adolescent autonomy, and adolescents' reduced social and emotional dependence on parents; Collins & Laursen, 1992; Conger & Ge, 1999; Ge, Conger, & Elder, 1996) as well as dispositional and parenting factors (e.g., temperament, maternal conflict reactions; see Eisenberg et al., 2008). The nature and extent of adolescent–parent conflict varies within families, and although conflict can emerge over issues of "critical" importance and/or urgency, disagreements over everyday "trivial" matters (e.g., chores, curfew) are often the root of adolescent–parent conflict (Smetana, 1996). Interestingly, although conflict often places stress on adolescents and their parents, researchers believe that conflict is part of an adaptive socialization process that promotes adolescent and parent development (Adams & Laursen, 2007; Collins & Laursen, 1992; Smetana, Campione-Barr, & Metzger, 2006).

Although a wealth of evidence indicates that adolescents' conflict with parents is common and developmentally significant, the social-cognitive *aftereffects* of conflict are not well understood. For example, it is reasonable to believe that adolescents and parents remember specific conflict incidents over time, but is their memory for conflict an accurate representation of how they initially perceived the conflict, and how does it mesh with observer ratings of the conflict? A large and convergent body

of literature indicates that memories may not always be accurate depictions of interpersonal experience (Baldwin, 1995; Fiske & Taylor, 1991). Thus, over time, when the memory for a conflict event degrades (i.e., as individuals forget the details of these specific interactions), how do adolescents and parents ''fill in the gaps'' or *reconstruct* their memory for the details of the conflict? Grotevant (1998), in his discussion of adolescent–parent relationships, has suggested that it is important to consider ''the ways in which individuals frame events and reconstruct their own pasts . . . even if these reconstructions are not completely faithful to history'' (p. 1126). Moreover, this question about reconstructive memory for conflict has important implications for how adolescent–parent conflict is both understood and treated by researchers and practitioners.

Using Bowlby's (1969/1982, 1973) attachment theory as a conceptual framework, Feeney and Cassidy (2003) began to address novel questions about reconstructive memory for adolescent–parent conflict. They proposed that the way in which adolescents reconstruct their memory for adolescent–parent conflict is governed in part by their internal working models of attachment, which are internalized mental representations of attachment experiences forged through repeated daily secure base interactions with parents and other caregivers (Bowlby, 1973). If these models provide rules for the direction of memory for attachment-related information (as Bowlby, 1973, and Main, Kaplan, & Cassidy, 1985, claimed), then adolescents might tap into these models to reconstruct the degraded memory of their conflicts with parents. More precisely, if these internal working models are secure, adolescents should be inclined to reconstruct their memory for adolescent–parent conflict such that they remember these interactions as more positive than they did in their original perceptions (i.e., in a more positive and less negative manner), because they are relying on secure internalized attachment representations. In contrast, if these models are insecure, adolescents should reconstruct their memory for conflictual interactions, such that they will remember these interactions as more negative than their original perceptions (e.g., in a more negative and less positive manner) because they are relying on insecure attachment representations. These propositions are consistent with other theories suggesting that individuals recall events from memory in ways that reflect their views and perceptions (see Pasupathi, 2001; Tversky & Marsh, 2000), and broader theories that individuals' mental representations mediate longitudinal connections between early experience and later functioning (see Dweck & London, 2004).

The first empirical examination of these ideas did not focus on individuals' attachment organization (described next) but instead involved the use of adolescents' self-reported attachment-related representations of their mothers and fathers. Feeney and Cassidy's (2003) results from both their initial study and a replication study revealed that, as expected, adolescents reconstructed their memory of adolescent–parent conflict over time as a function of their representations of a particular parent. For example, in relation to separate laboratory-based conflict discussions with mothers and fathers, when adolescents' perceptions of the parent were more negative (e.g., as adolescents responded to questionnaires by describing their mothers or fathers as unavailable for help when needed or as not understanding their feelings), adolescents were more likely to remember the discussion with that particular parent as *less positive* and *more negative* than reported 6 weeks earlier, just after the conflict episode.

In light of this intriguing evidence that adolescents reconstruct their memory for adolescent–parent conflict as a function of their representations of parents, the purpose of the present investigation was to use Feeney and Cassidy's (2003) sample to extend this novel line of research in three noteworthy ways. First, Feeney and Cassidy examined adolescents' self-reported representations of each parent in relation to a conflict interaction with that particular parent (e.g., asking whether an adolescent's representation of mother is linked to the adolescent's memory for a conflict task with her). In the present investigation, instead of examining adolescents' representations of each specific parent, we examined whether and how adolescents' Adult Attachment Interview (AAI; George, Kaplan, & Main, 1996) classifications, which were not available at the time of the Feeney and Cassidy report, were linked to adolescents' memory for conflict with parents. Our use of the AAI in this investigation is both conceptually and methodologically distinct from Feeney and Cassidy's earlier work because the AAI taps an adolescent's attachment organization (referred to as the individual's ''current state of mind with respect to attachment''; Main & Goldwyn, 1998) rather than representations of individual parents. This ''current state of mind'' is thought to be a relatively stable global attachment organization that emerges in adolescence based on the consolidation and integration of internalized experiences with mother, father, and other attachment figures (Allen, 2008; Allen, Boykin-McElhaney, Kuperminc, & Jodl, 2004; Bretherton & Munholland, 1999, 2008; Hesse, 1999, 2008). Thus, from a theoretical perspective, this study permits examination of one of the core propositions of attachment theory (Bowlby, 1973): the idea that a link exists between attachment and the processing of social information. This proposition is supported by considerable empirical evidence from studies of both children and adults (e.g., Belsky, Spritz, & Crnic, 1996; Kirsh & Cassidy, 1997; van Emmichoven, van IJzendoorn, de Ruiter, & Brosschot, 2003). Yet, despite the fact that this proposition is so theoretically central, researchers have examined it surprisingly little, especially during adolescence (see Dykas & Cassidy, 2007, for a review). Moreover, from a methodological perspective, the findings related to the AAI can be compared and contrasted to the many other AAI-related findings in the literature.

Second, we extend the Feeney and Cassidy (2003) study by examining not only how attachment is linked to *adolescents'* reconstructive memory for conflict, but also to *mothers'* and *fathers' reconstructive memory*. Researchers have shown considerable interest in understanding whether and how parental cognitions influence child functioning (e.g., Bugental & Happaney, 2002) and a central component of attachment theory is the notion that the way in which parents process attachment-related information contributes to their children's quality of attachment to them, mediated largely by parenting behavior (Bowlby, 1988; van IJzendoorn, 1995; see also George & Solomon, 2008). It is thought, for example, that parents who process information about their children in a negatively biased way will have difficulty serving as a secure base and/or safe haven for their children. This lack of a parental secure base and/or safe haven, in turn, is thought to contribute to an insecure attachment. There is considerable evidence that parents' representations of their children are related to their parenting behavior and/or their children's attachment to them (Benoit, Parker, & Zeanah, 1997; Grienenberger, Kelly, & Slade, 2005; Slade, Belsky, Aber, & Phelps, 1999; see George & Solomon, 2008, for a review), yet to our knowledge no published study has examined links between adolescent attachment and parents' reconstructive memory, or social information processing more generally. Importantly, we note that simply the inclusion of fathers in the present investigation is in itself an advance over nearly all adolescent attachment research, which has largely focused on mothers (see Grotevant, 1998, for discussion of the importance of including fathers in developmental research).

Finally, we extend Feeney and Cassidy's (2003) previous work by investigating how memory for adolescent–parent conflict relates to the *observed behavioral quality* of the conflict as a function of adolescent attachment organization. More precisely, using observational data collected during the adolescent–parent conflict interactions, which were not available at the time of the Feeney and Cassidy report, we were able to discern whether insecure and secure adolescents' (as well as their parents') memory for conflict became more or less attuned over time to observer ratings of behaviors exhibited in the conflict. This final research extension is of considerable theoretical interest because it lends additional insight into whether memory for adolescent–parent conflict, over time, converges or diverges from the observed behavior during the conflict interaction as a function of adolescents' attachment organization. For example, it is possible that a secure or an insecure individual could have an overly favorable or unfavorable initial memory of an event in comparison to observers that ultimately becomes more attuned to the observed quality of the event over some time period. On the other hand, it is possible that an individual's view of an event could initially match observers' perspectives on the event, but later memory could diverge from the observers' perspective.

On the basis of both attachment theory and Feeney and Cassidy's (2003) earlier findings, we examined the following two hypotheses. First, we hypothesized that the memory processes of secure and insecure adolescents differ, such that secure adolescents are more likely to have a bias to remember adolescent–parent conflictual interactions more positively and less negatively over time; in contrast, insecure adolescents were hypothesized to have a bias to remember the conflict interaction more negatively and less positively over time. Second, we hypothesized that the memory processes of parents of secure and insecure adolescents differ, such that parents of secure adolescents are more likely to have a bias to remember the adolescent–parent conflictual interactions less negatively and more positively over time; in contrast, parents of insecure adolescents were hypothesized to show a bias to remember the conflict interaction more negatively and less positively over time. For each hypothesis, we conducted accompanying examinations to investigate an additional research question about whether insecure and secure adolescents' (and their parents') memory for conflict becomes less or more attuned over time to the coder-rated behaviors exhibited in the conflict. In each analysis, we included adolescent gender as an additional factor, given an interest in studying unique characteristics of specific parent–adolescent dyads (e.g., mother–daughter, father–son; see Russell & Saebel, 1997).

Method

Participants

Participants were 189 eleventh-grade students recruited from seven public suburban high school and their parents. (We combined the cohorts in Feeney & Cassidy, 2003, Study 1 and Study 2 to obtain greater statistical power; see Table 1 for sample demographic information.) Data reported in this investigation were gathered from a larger study of adolescents' social relationships. Because of a focus on adolescent relationships with both mothers and fathers, we recruited English-speaking participants with married parents. Adolescents were paid $125 for participating in the larger study. Sample size varies across analyses due to missing data.

Procedure

We gathered data during three sessions spanning approximately 6 weeks. First, adolescents visited our laboratory and engaged, separately with their mother and father, in 10-min conflict discussions. Adolescents and their parents used a checklist to rate how much they disagreed with each other about 19 topics that parents and teens frequently disagree about, such as "chores," "homework," and "talking back to parents." A research assistant chose three topics for the mother–adolescent discussion and three topics for the father–adolescent discussion, selecting topics that were rated by the parent and adolescent as high in disagreement (see Feeney & Cassidy, 2003, for a further description of the generation of adolescent–parent conflict discussions). The order in which adolescents participated in the discussions with each parent was counterbalanced, and all discussions were videotaped for later coding. After each discussion, adolescents and parents completed the Emotional Response to Conflict Scale (ERCS; Cassidy, 1998; T1); adolescents also completed the vocabulary subtest of the Shipley Institute of Living Scale (Shipley, 1946) during this first session. In the second session (1 month later), adolescents completed the AAI in a different university laboratory room. Finally, 6 weeks after the adolescent–parent conflict discussions, we mailed a follow-up ERCS (T2) to adolescents and their parents. Participants were asked to complete questionnaires independently and to return them via mail in the envelope provided.

Table 1
Sample Characteristics

	Total ($n = 189$)
Adolescent gender (%)	
Male	38
Female	62
Family race (%)	
White/Caucasian	73
Black/African American	14
Asian	10
Hispanic	3
Annual household income (%)	
–$60,000	15
$61,000+	85
Mother education (%)	
High school	23
College/graduate degree	77
Father education (%)	
High school	18
College/graduate degree	82
Adolescent Shipley scores	$M = 29, SD = 4.8$

Measures

Emotional Response to Conflict Scale (Cassidy, 1998). This 31-item scale was designed to assess individuals' emotional responses to a 10-min laboratory conflict discussion task (Strodtbeck, 1951), both immediately afterward in the laboratory, and 6 weeks later at home. The items contained in this questionnaire fell into eight indices that, following Feeney and Cassidy (2003), we subsequently reduced into three summary scores (see Feeney & Cassidy, 2003, for a full description of the ERCS and for the theoretical and factor analytic basis of this data-reduction strategy). First, we created a *positive interaction* score by averaging the items in the positive discussion, own positive emotions, other positive emotions, and positive treatment indices (mean $\alpha = .87$). Second, we created a *negative interaction* score by averaging the items in the negative discussion, own negative emotions, and other negative emotions indices (mean $\alpha = .84$). Finally, we created a *hostile treatment* score by averaging the hostile treatment item ratings (mean $\alpha = .76$). For the entire sample across both time points, associations between these three summary scores ranged from $r = -.42$ (positive interaction and hostile treatment scores) to $r = .66$ (negative interaction and hostile treatment scores).

Adolescent–Parent Conflict Interaction Coding System (Ziv, Cassidy, & Ramos-Marcuse, 2002). We used this coding system, based in part on an earlier system developed by Kobak, Cole, Ferenz-Gillies, Fleming, and Gamble (1993), to assess adolescent and parent verbal and nonverbal (e.g., facial) behavior during a 10-min laboratory discussion task. In this study, we analyzed scales assessing adolescent *secure base use* (i.e., the degree to which the adolescent maintained "secure relatedness" during the discussion through the demonstration of relationship-maintaining behaviors even when under the stress of discussing a disagreement) and parents' secure base provision (i.e., the degree to which the parent was sensitive, responsive, and available to the adolescent throughout the conflict discussion). We also analyzed separate scales for adolescents and their parents that assessed each individual's *avoidance of discussing disagreement* (i.e., the overall degree to which the individual actively disengaged from the discussion of conflict) and *hostility* (i.e., the overall degree to which the individual engaged in sarcastic/contemptuous comments or smiles, dysfunctional anger, disgust, and/or aggressive posturing). Finally, we analyzed the *open communication* dyadic scale that assessed the overall degree to which the adolescent–parent dyad demonstrated comfort and openness in discussing their thoughts, feelings, and emotions during the conflict in a mutually cohesive and fluid manner. All of these scales were based on a 7-point rating system (with appropriate behavioral anchors); six highly trained coders, blind to additional data regarding the participants, independently rated videotaped discussions. Agreement was assessed continuously throughout the coding period and at least two coders coded a randomly selected 17% of adolescent–mother interactions ($n = 32$) and 16% of father–adolescent interactions ($n = 31$). Sufficient reliability emerged for this group of coders: Intraclass correlation coefficients ranged from .76 on mothers' secure base provision to .84 on adolescents' hostility toward father. Disagreements were conferenced and consensus scores were used in all analyses.

Because high correlations emerged within and between the adolescent and parent behavior scale score sets (*r*s ranging from −.22 to .81), we conducted principal component analyses (PCAs) to combine these data. (We conducted separate PCAs for behaviors rated in the adolescent–mother conflict and for the behaviors rated in the adolescent–father conflict. We did not include participants' behavioral hostility scores in these PCAs because they corresponded directly to the hostile treatment scores derived from the ERCS.) In the PCA for adolescent–mother conflict, all behaviors loaded onto a single factor explaining 68.7% of the variance (eigenvalue = 2.75). Similarly, in the PCA for adolescent–father conflict, all behaviors loaded onto a single factor explaining 64.1% of the variance (eigenvalue = 2.56). On the basis of these two PCAs and the positively scaled factor loadings, we computed standardized factor scores based on the factor loadings, which we labeled *positive adolescent–mother dyadic conflict behavior* scores and *positive adolescent–father dyadic conflict behavior* scores.

Adult Attachment Interview (George et al., 1996). We used this well-known semistructured interview to assess adolescents' "current state of mind with respect to attachment," focusing principally on memories of attachment-related experiences during childhood (see Hesse, 1999, 2008, for full descriptions of the AAI). Interviews lasted approximately 1 hr and were audiotaped for later verbatim transcription. We made minor modifications to this interview to make some of the questions more appropriate for an adolescent population (Allen, Moore, Kuperminc, & Bell, 1998). The psychometric properties of the AAI have been well established (see Hesse, 1999, 2008). Although the AAI was originally developed to assess adult attachment, a wealth of research indicates that the AAI is a valid measure of adolescents' attachment representations as well (see Allen, 2008, for a review). Moreover, the AAI has shown considerable test–retest reliability in several short-term and long-term longitudinal studies (see Hesse, 1999, 2008), and Allen et al. (2004) reported that AAI attachment security is stable across adolescence. Following Allen (2008), we assumed that all adolescents in this study possessed a "current state of mind with respect to attachment" that could be assessed using the AAI.

Using Main and Goldwyn's (1998) classification system, coders rated each transcript on a series of 9-point scales. Coders used inferred experience scales to rate the likely quality of adolescents' childhood attachment-related experiences, and "state of mind" scales (e.g., coherence of mind) to assess adolescents' current state of mind with respect to attachment. Based on an integrated consideration of both the adolescents' inferred experiences and state of mind, coders assigned one of four principal classifications to the transcript. Adolescents classified as secure/autonomous coherently described various childhood experiences, valued attachment relationships, and considered attachment-related experiences as important to personal development. Adolescents classified in any of the three insecure groups demonstrated an inability to describe their childhood attachment-related experiences coherently. Specifically, adolescents classified as insecure/dismissing were derogatory about the importance of attachment and/or dismissed the impact that early negative experiences had on personal development and on attachment relationships. Adolescents classified as insecure/preoccupied demonstrated an excessive, confused/passive, and nonobjective preoccupation with attachment relationships and/or experiences. Adolescents classified as insecure/unresolved revealed lapses in the monitoring of reasoning or discourse when discussing loss or trauma. When transcripts could not be placed into any other category, they were labeled ''insecure/cannot classify.''

Four coders who were trained and certified as reliable by Mary Main and Erik Hesse (developers of and/or experts on the AAI and classification system) coded the AAI transcripts. All four coders were blind to additional information regarding participants. Interrater reliability among these coders was assessed continuously throughout coding; a randomly selected 29% of cases ($n = 55$) were coded by at least two coders (78% agreement, $\kappa = .61$, $p < .05$). All disagreements were resolved by a fifth independent coder who coded no additional data.

Shipley Institute of Living Scale (Shipley, 1946). This 40-item vocabulary subtest, in which adolescents were asked to select the correct synonym from a list of four possibilities, was used to assess adolescents' verbal knowledge (to determine whether it was related to adolescents' AAI group classifications). The psychometric properties of this measure are well established (Kirk & Rattan, 1992).

Results

Descriptive Statistics

AAI classifications. The distribution of the adolescent AAI classifications was: 126 secure/autonomous (67%), 44 insecure/dismissing (23%), 10 insecure/preoccupied (5%), 6 unresolved (3%), and 2 insecure/cannot classify (1%). (Scheduling difficulties prohibited 1 adolescent from completing the AAI.) This distribution is similar to distributions obtained in other studies of low-risk adolescents (e.g., Ammaniti, van IJzendoorn, Speranza, & Tambelli, 2000; Bakermans-Kranenburg & van IJzendoorn, 2009; Scharf, 2001). Because there were few adolescents in the insecure groups, we combined these groups into one insecure group and examined secure versus insecure AAI group differences. Adolescents' AAI group classifications were not linked to their Shipley vocabulary scores, $t(173) = 1.56$, $p = .12$.

ERCS and conflict behavior scores. We present descriptive statistics for participants' initial and follow-up ERCS scores in Table 2.

Test of Hypotheses Related to Reconstructive Memory for Adolescent–Parent Conflict

To test our hypotheses about attachment-related differences in reconstructive memory for adolescent–parent conflict, we conducted a series of general linear mixed model analyses using the Proc Mixed procedure in SAS/STAT® software (Version 9.1). In these analyses, the repeated factor was participants' T1 and T2 ERCS summary scores. The fixed factors were the time at which participants completed the ERCS (i.e., ERCS Time; two levels: T1 vs. T2), Reporting Family Member (four levels: adolescent reporting about teen–mother conflict, adolescent reporting about teen–father conflict, mother, and father), Adolescent Gender (two levels:

Table 2
Descriptive Statistics for Adolescents' and Parents' ERCS Scores

	Initial (T1)		Follow-up (T2)	
Variable	*M*	*SD*	*M*	*SD*
Adolescent ERCS scores for adolescent–mother conflict				
Positive interaction	3.36	0.94	3.32	0.80
Negative interaction	1.79	0.76	1.65	0.68
Hostile treatment	1.29	0.57	1.27	0.51
Adolescent ERCS scores for adolescent–father conflict				
Positive interaction	3.29	0.83	3.25	0.83
Negative interaction	1.78	0.68	1.60	0.67
Hostile treatment	1.27	0.41	1.26	0.44
Mother ERCS scores for adolescent–mother conflict				
Positive interaction	3.24	0.90	3.23	0.83
Negative interaction	1.67	0.73	1.67	0.70
Hostile treatment	1.41	0.73	1.38	0.63
Father ERCS scores for adolescent–father conflict				
Positive interaction	3.37	0.79	3.31	0.73
Negative interaction	1.65	0.66	1.65	0.59
Hostile treatment	1.39	0.66	1.41	0.61

Note. ERCS initial (T1) *n*s range from 180 to 189. ERCS follow-up (T2) *n*s range from 151 to 160. ERCS = Emotional Response to Conflict Scale.

boy vs. girl), and Adolescent Attachment (two levels: secure vs. insecure). We also added a "family" random effect in our analyses to account for any correlations among ERCS scores obtained from participants within the same family. We included all main effects and first-, second-, and third-order interactions in our analyses.

The results of interest in these mixed model analyses were whether the ERCS Time × Attachment Group interactions (and accompanying post hoc analyses examining T1/T2 differences) were significant for each reporting family member and whether different patterns of gender-related results emerged with regard to adolescent boys and/or girls. To obtain these particular results, we tested the simple interaction effects of ERCS Time × Adolescent Attachment Group within both the three-way ERCS Time × Adolescent Attachment Group × Reporting Family Member interactions and the four-way ERCS Time × Adolescent Gender × Adolescent Attachment Group × Reporting Family Member interactions. Then, when significant simple ERCS Time × Adolescent Attachment Group interaction effects emerged and subsequent post hoc tests provided evidence that change did indeed occur (i.e., significant attachment-related differences emerged between participants' T1 and T2 ERCS scores), we plotted participants' ERCS scores and conducted accompanying t tests to describe *how*, on average, family members' perceptions of conflict changed over a span of 6 weeks as a function of adolescent attachment and/or adolescent gender.

Moreover, for each of these examined significant interactions, we conducted further follow-up analyses to determine how participants' perceptions of the conflict converged or diverged from the behavioral ratings of the adolescent–parent conflict interactions over the 6-week period. These follow-up analyses mirrored the mixed model analyses described earlier, except that the repeated factor was two difference scores that represented the difference between participants' ERCS summary scores and our behavioral rating scores (one score for T1 perceptions and another for T2 perceptions). We calculated these difference scores by first standardizing participants' ERCS summary scores and behavioral hostility scores (behavioral conflict scores had already been standardized during the PCAs). We then subtracted each participant's behavior scores from his or her corresponding ERCS summary scores (i.e., ERCS positive interaction score − positive adolescent–parent dyadic conflict behavior scores; ERCS negative interaction score − positive adolescent–parent dyadic conflict behavior scores [reverse scored]; ERCS hostile treatment score − behavioral hostility score). Thus, for positive interaction, a positive (i.e., nonnegative) difference score demonstrated that the reporting family member perceived the conflict more favorably than did observers, and a negative (i.e., nonpositive) difference score demonstrated that the reporting family member perceived the conflict in a less favorable way than did observers. In contrast, for negative interaction and hostile treatment, a positive (i.e., nonnegative) difference score demonstrated that the reporting family member perceived the conflict less favorably than did observers, and a negative (i.e., nonpositive) difference score demonstrated that the reporting family member perceived the conflict in a more favorable way than did observers. Using these mixed model analyses and accompanying t tests, we were able to determine whether (a) difference scores were significantly different from zero (i.e., a significant difference score indicated that the reporting family members' perceptions and our behavioral ratings were significantly different), and (b) whether corresponding T1- and T2-related *difference scores* differed significantly (i.e., a significant difference in the difference scores indicated that that there was a significant change in the degree to which the T2 and T1 scores diverged from observer ratings provided at T1). In the next two sections, we present our results by hypothesis. In light of Roisman, Fraley, and Belsky's (2007) recent suggestions that individual differences in the AAI should also be examined continuously, we examined whether and how adolescents' reliable AAI coherence of mind scores were linked to adolescent and parent reconstructive memory for conflict. As expected, these results (which are available from M. J. Dykas) were substantively similar to the AAI group classification results reported in this article.

> *Hypothesis 1: Adolescent attachment security is linked to more positively and less negatively biased adolescent reconstructive memory for adolescent–parent conflict over time, whereas adolescent attachment insecurity is linked to less positively and more negatively biased memory over time.*

With respect to *adolescent–mother conflict*, a significant ERCS Time × Attachment simple interaction effect emerged for adolescents' ERCS negative interaction scores, $F(3, 701) = 5.23$, $p < .01$, but not ERCS positive interaction, $F(3, 699) = 1.90$, $p = .12$, or hostile treatment scores, $F(3, 767) = 1.61$, $p = .18$: Secure adolescents showed a significant decrease in their propensity to remember the conflict as negative, $M_{T1-T2} = 0.21$, $SE = 0.06$, $t_{T2-T1}(611) = 3.70$, $p < .001$, $g = .14$ (see Figure 1). For this t test and all other t tests reported in this section, the degrees of freedom were derived from the omnibus mixed model analysis. Moreover, the measure of effect size is reported as Hedge's g (see Cooper & Hedges, 1994). In contrast, insecure adolescents' memory for the negative features of the conflict remained stable during the 6-week period, $M_{T1-T2} = 0.03$, $SE = 0.08$, $t_{T2-T1}(598) = 0.37$, $p = .71$, $g = .02$; see also Figure 1. Inspection of the difference scores between secure adolescents' T1 and T2 ERCS negative interaction scores and their reverse-scored positive adolescent–mother dyadic conflict behavior scores indicated that secure adolescents' perceptions of the negative features of the conflict were initially significantly less negative than the observed behavioral ratings at T1, $M_{DiffT1} = -1.41$, $SE = 0.10$, $t(503) = -13.39$, $p < .001$, $g = .63$, and continued to diverge significantly and become even less negative than the behavioral ratings 6 weeks later at T2, $M_{DiffT2} = -1.73$, $SE = 0.11$, $t(499) = -15.31$, $p < .001$, $g = .70$; $M_{DiffT1-DffT2} = 0.32$, $SE = 0.08$, $t_{T1-T2}(572) = 3.74$, $p < .001$, $g = .17$. Insecure adolescents' perceptions of the negative features of the conflict were also initially significantly less negative than the behavioral ratings at T1, $M_{DiffT1} = -1.59$, $SE = 0.15$, $t(503) = -10.65$, $p < .001$, $g = .47$, and T2, $M_{DiffT2} = -1.63$, $SE = 0.16$, $t(476) = -10.38$, $p < .001$, $g = .47$, but did not diverge significantly from our behavioral ratings over the 6-week period, $M_{DiffT1-DffT2} = 0.04$, $SE = 0.12$, $t_{T1-T2}(562) = 0.36$, $p = .72$, $g = .01$.

With respect to *adolescent–father conflict*, a significant ERCS Time × Attachment simple interaction effect emerged for both adolescents' ERCS positive interaction scores, $F(3, 707) = 3.49$, $p < .05$, and ERCS negative interaction scores, $F(3, 709) = 4.91$, $p < .01$, but not for adolescents' ERCS hostile treatment scores, $F(3, 773) = 0.20$, $p = .90$. Regarding adolescents' positive interaction scores, secure adolescents' memory remained stable during the 6-week period, $M_{T1-T2} = 0.03$, $SE = 0.06$, $t_{T1-T2}(633) = 0.45$, $p = .65$, $g = .02$, whereas insecure adolescents showed a significant decrease in their propensity to remember the conflict as positive, $M_{T1-T2} = 0.21$, $SE = 0.09$, $t_{T1-T2}(620) = 2.46$, $p < .05$, $g = .09$ (see Figure 2). Inspection of the difference scores between secure adolescents' T1 and T2 ERCS positive interaction scores and their positive adolescent–father dyadic conflict behavior scores indicated that secure adolescents' perceptions of the positive features of the conflict did not differ from the observed behavioral ratings at T1, $M_{DiffT1} = -0.01$, $SE = 0.10$, $t(508) = -0.05$, $p = .96$, $g = .01$, or T2, $M_{DiffT2} = -0.05$, $SE = 0.11$, $t(502) = -0.44$ $p = .66$, $g = .02$, and did not diverge from the behavioral ratings over time, $M_{DiffT1-DffT2} = 0.04$, $SE = 0.08$, $t_{T1-T2}(617) = 0.58$, $p = .56$, $g = .02$. Insecure adolescents' perceptions of the positive features of the conflict also did not differ significantly from the observed behavioral ratings at T1, $M_{DiffT1} = 0.20$, $SE = 0.15$, $t(502) = 1.36$, $p = .17$, $g = .06$, or T2, $M_{DiffT2} = -0.06$, $SE = 0.16$, $t(472) = -0.39$, $p = .70$, $g = .02$, but there was a significant change in insecure adolescents' perceptions with

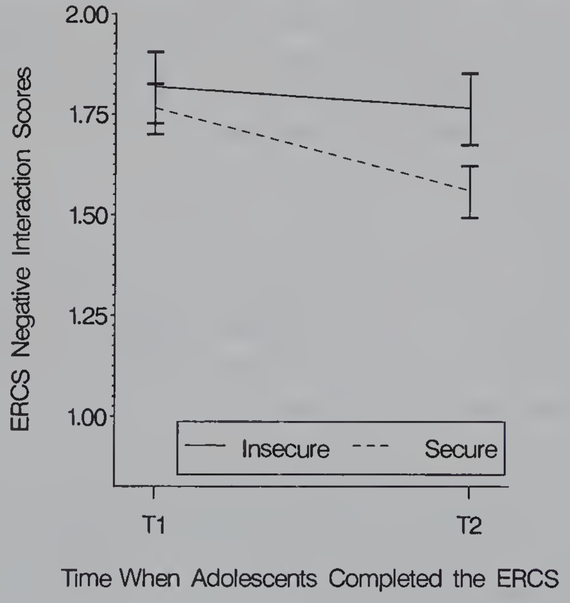

Figure 1. Adult Attachment Interview–related changes in adolescents' Emotional Response to Conflict Scale negative interaction scores for their conflict discussions with mother.

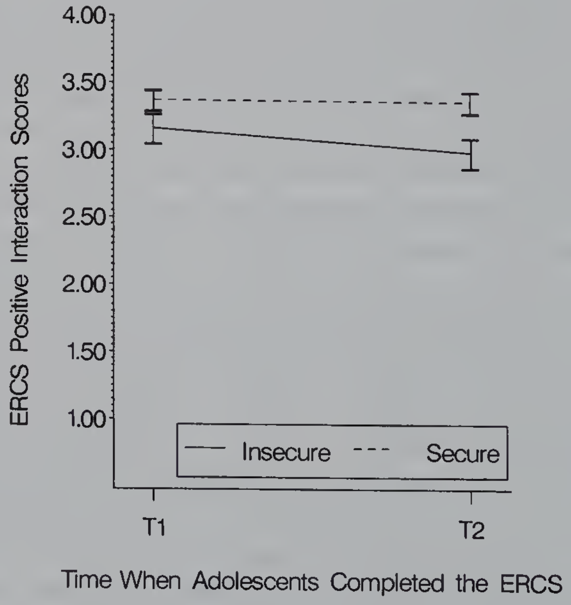

Figure 2. Adult Attachment Interview–related changes in adolescents' Emotional Response to Conflict Scale positive interaction scores for their conflict discussions with father.

respect to the behavioral ratings over time. More precisely, insecure adolescents' ratings shifted from being more positive to less positive over the 6-week period compared with the behavioral ratings, $M_{\text{DiffT1–DffT2}} = 0.26$, $SE = 0.10$, $t_{\text{T1–T2}}(607) = 2.55$, $p < .01$, $g = .11$.

Regarding adolescents' ERCS negative interaction scores for father, secure adolescents showed a significant decrease in their propensity to remember the conflict with their fathers as negative, $M_{\text{T1–T2}} = 0.17$, $SE = 0.06$, $t_{\text{T1–T2}}(617) = 2.96$, $p < .01$, $g = .11$, whereas insecure adolescents' memory for the negative features of the conflict remained stable during the 6-week period, $M_{\text{T1–T2}} = 0.15$, $SE = 0.08$, $t_{\text{T1–T2}}(601) = 1.92$, $p = .06$, $g = .08$ (see Figure 3). Inspection of the difference scores between secure adolescents' T1 and T2 ERCS negative interaction scores and their reverse-scored positive adolescent–father dyadic conflict observed behavior scores indicated that secure adolescents' perceptions of the negative features of the conflict were significantly less negative than the behavioral ratings at T1, $M_{\text{DiffT1}} = -1.53$, $SE = 0.11$, $t(515) = -14.23$, $p < .001$, $g = .61$, and later diverged significantly and became even less negative than the behavioral ratings 6 weeks later at T2, $M_{\text{DiffT2}} = -1.77$, $SE = 0.12$, $t(517) = -15.36$, $p < .001$, $g = .65$; $M_{\text{DiffT1–DffT2}} = 0.24$, $SE = 0.09$, $t_{\text{T1–T2}}(578) = 2.80$, $p < .01$, $g = .11$. Insecure adolescents' perceptions of the negative features of the conflict were also initially significantly less negative than the observed behavioral ratings at T1, $M_{\text{DiffT1}} = -1.73$, $SE = 0.15$, $t(510) = -11.46$, $p < .001$, $g = .51$, and T2, $M_{\text{DiffT2}} = -1.94$, $SE = 0.16$, $t(485) = -12.21$, $p < .001$, $g = .55$, but did not diverge significantly farther from the behavioral ratings over time, $M_{\text{DiffT1–DffT2}} = 0.21$, $SE = 0.12$, $t_{\text{T1–T2}}(565) = 1.80$, $p = .07$, $g = .07$.

> *Hypothesis 2: Adolescent attachment security is linked to more positively and less negatively biased parental reconstructive memory for adolescent–parent conflict over time, whereas adolescent attachment insecurity is linked to more negatively and less positively biased parental memory over time.*
